Research Paper

The Effect of Lunarlike Satellites on the Orbital Infrared Light Curves of Earth-Analog Planets

Nicholas A. Moskovitz,1 Eric Gaidos,2 and Darren M. Williams3

Abstract

We have investigated the influence of lunarlike satellites on the infrared orbital light curves of Earth-analog extrasolar planets. Such light curves will be obtained by NASA’s Terrestrial Planet Finder (TPF) and ESA’s Darwin missions as a consequence of repeat observations to confirm the companion status of a putative planet and determine its orbit. We used an energy balance model to calculate disk-averaged infrared (bolometric) fluxes from planet-satellite systems over a full orbital period (one year). The satellites are assumed to lack an atmosphere, have a low thermal inertia like that of the Moon, and span a range of plausible radii. The planets are assumed to have thermal and orbital properties that mimic those of Earth, while their obliquities and orbital longitudes of inferior conjunction remain free parameters. Even if the gross thermal properties of the planet can be independently constrained (e.g., via spectroscopy or visible-wavelength detection of specular glint from a surface ocean), only the largest (~Mars-sized) lunarlike satellites can be detected by light curve data from a TPF-like instrument (i.e., one that achieves a photometric signal-to-noise ratio of 10 to 20 at infrared wavelengths). Nondetection of a lunarlike satellite can obfuscate the interpretation of a given system’s infrared light curve so that it may resemble a single planet with high obliquity, different orbital longitude of vernal equinox relative to inferior conjunction, and in some cases drastically different thermal characteristics. If the thermal properties of the planet are not independently established, then the presence of a lunarlike satellite cannot be inferred from infrared data, which would thus demonstrate that photometric light curves alone can only be used for preliminary study, and the addition of spectroscopic data will be necessary. Key Words: Planetary systems—Planets and satellites: general—Astrobiology—Methods: data analysis. Astrobiology 9, xxx–xxx.

1. Introduction

Planets with a minimum mass of 5–6 Earth masses have recently been detected around low-mass stars (Rivera et al., 2005; Udry et al., 2007), and it seems likely that observatories such as CoRoT or Kepler will detect yet smaller planets (Gillon et al., 2005). Space-based observatories of the future will be capable of directly detecting Earth-sized planets around other stars. Proposed missions include a coronagraph that operates at visible wavelengths (TPF-C) (Traub et al., 2006) and a large-baseline interferometer that operates in the infrared (TPF-I and Darwin) (Fridlund, 2000; Beichman et al., 2006). One goal of such missions is to directly detect Earth-sized planets around other stars. Proposed missions include a coronagraph that operates at visible wavelengths (TPF-C) (Traub et al., 2006) and a large-baseline interferometer that operates in the infrared (TPF-I and Darwin) (Fridlund, 2000; Beichman et al., 2006). One goal of such missions is to distinguish between planets that are Earth-like and can support life and those that are decidedly less so (e.g., analogues to Mercury, Venus, or Mars). Several techniques have been proposed to carry out this classification. Spectroscopy can reveal the presence of atmospheric gases, such as H2O, CH4, and O2, which are indicative of temperate conditions or biological activity, or both (Des Marais et al., 2002). Photometry in reflected light can reveal diurnal (rotational) variability associated with ice, oceans, land, and vegetation across the surface of a planet if no clouds are present (Ford et al., 2001). The specular “glint” from oceans might be detected as an increase in the visible flux and polarization of reflected light at large phase angles (McCullough, 2008; Williams and Gaidos, 2008). Selsis (2004) showed that orbital infrared light curves could reveal general thermal properties of terrestrial planets. Gaidos and Williams (2004) showed that diurnally averaged orbital light curves at thermal infrared wavelengths contain information about the thermal
properties of the planet's emitting layer (surface or clouds) and obliquity. Such light curves would be generated as a by-product of repeated observations to confirm the companion status and orbit of a putative planet and function as a first step toward characterization. One finding of Gaidos and Williams (2004) was that oceans or a thick atmosphere damp seasonal variations in temperature and that low or no variability in a planet's infrared light curve is indicative of the presence of oceans or a thick atmosphere. In conjunction with other characteristics, this is a signature of habitable surface conditions. These authors and the work presented here do not consider the effects of variable cloud cover.

The disk-averaged infrared flux of an orbiting planet can vary, as it presents different phases to a distant observer. This phenomenon has been observed for Jupiter-mass extrasolar planets with semi-major axes much less than 1 AU (Harrington et al., 2006; Cowan et al., 2007; Knutson et al., 2007). The variation in flux from a planet depends on the diurnal pattern of outgoing infrared flux from the emitting surface (either the top of the atmosphere, if any is present, cloud layers, or the surface), which is controlled by the planet's thermal properties and day length. In general, significant day-night temperature differences will occur only if

$$\cos \theta \lesssim \left( \frac{\partial I}{\partial T} \right)_T$$

where $c$ is the heat capacity of the surface/atmosphere, $\omega$ is the angular rotation rate, and the right-hand side is the slope of the outgoing bolometric infrared flux at the emitting surface vs. temperature, $T$, evaluated at the mean surface temperature of the body. For Earth, $c = 8.34 \times 10^7 \text{ J m}^{-2} \text{ K}^{-1}$ and $\partial I / \partial T = 1.58 \text{ W m}^{-2} \text{ K}^{-1}$ for $T = 288 \text{ K}$ (however, the effective emitting temperature of Earth is 255 K). Thus Eq. 1 does not hold for Earth: Earth's day-night temperature variation is small, as it would be for any Earth-like planet with a rotation period much less than a year. This is primarily due to the high heat capacity of the ocean mixed layer, which also moderates surface temperatures over landmasses and controls the outgoing infrared flux budget.

The primordial rotation periods of terrestrial planets are thought to be a stochastic outcome of the final stages of formation by accretion of planetary embryos and will be on the order of hours to days (Lissauer et al., 2000). As a consequence, the disk-averaged infrared flux from an Earth-like planet will only vary significantly along the orbit if the planet has a non-zero obliquity or eccentricity and, hence, seasons. This was explored in Gaidos and Williams (2004).

Earth's moon, lacking an atmosphere or oceans and having a lunar day 29.5 times longer than Earth, experiences a much larger diurnal surface temperature variation. Absence of recent geological activity on the Moon has allowed a regolith of impact ejecta to accumulate. This material is optically dark [the average lunar Bond albedo is 0.07 (Lane and Irvine, 1973) compared to Earth's 0.31] and has a relatively low heat capacity [that of the Moon is $4 \times 10^7 \text{ J m}^{-2} \text{ K}^{-1}$ at 29.5 days or 0.1% of Earth, (Muller and Lagerros, 1998)]. As a result, the inequality of Eq. 1 is satisfied; thus, the Moon makes a significant or even dominant contribution (depending upon viewing geometry) to the variable component of the infrared flux from the Earth-Moon system.

The Moon is thought to have accreted from a circumstellar disk of ejecta generated by the impact of a Mars-sized body (Hartmann, 1986). The high ambient temperatures and low gravity in the transient disk explain the Moon's lack of volatiles (Pritchard and Stevenson, 2000). Current scenarios for the final stages of terrestrial planet formation include such giant impacts (Canup and Agnor, 1998), and the results of numerical simulations suggest that they are not rare (Ida et al., 1997). Thus, large satellites that lack atmospheres or oceans may be common around extrasolar rocky planets. Like the Moon, these satellites would have originally formed closer to their parent planets, and their rotations would have quickly synchronized to their orbits (Gladman et al., 1996; Canup and Agnor, 1998). As a result, their diurnal temperature variation could be significant. We note that Moon-sized satellites could retain an atmosphere against gravitational escape over Ga timescales if one was originally present.

Satellites around extrasolar planets will be unresolved by even the most ambitious planet-finding mission; the angular separation of Earth and the Moon at a distance of 10 pc is 0.25 mas. However, a large satellite might reveal itself by a significant variation in the total (bolometric) flux from the system. Such an interpretation would require independent knowledge of the thermal and rotational properties of the parent planet, which can be established via spectroscopy (Des Marais et al., 2002; Selsis, 2004) or optical light curve data (McCullough, 2006; Williams and Gaidos, 2008). If establishment of these gross thermal properties leads to the expectation that infrared flux variation would be small (Eq. 1), then observation of significant variation could be attributed to the presence of a large satellite. In the absence of such auxiliary information, however, the satellite contribution may result in an assignment of erroneous thermal properties to the planet.

We present calculations of infrared light curves of an Earth-like planet with a Moon-like satellite. The terms Earth-like or Earth-analog refer to specific thermal and orbital properties that represent those of Earth (see Section 2). The albedo, heat capacity, and orbital period of the satellite are set to that of the Moon (see above), while its radius is allowed to vary.

In Section 2, we describe the details of the analytical energy balance model (EBM) used in these calculations. We give an illustrative calculation in Section 3. We then determine the minimum radius of a lunarlike satellite that can be detected at infrared wavelengths around an Earth-analog planet (Section 4). In Section 5, we describe the biases in planetary orbital properties that can be introduced by an undetected lunarlike satellite. In Section 6, we describe the effects that low- and high-altitude clouds would have on our calculations, and in Section 7 we discuss the implications of our results.

2. Model

Our calculations are based on the infrared orbital light curve model of Gaidos and Williams (2004). We employed a linearized, analytic EBM to calculate the infrared flux emitted by a planet. This model assumes a single, uniform planetary albedo and parameterizes the thermal inertia and meridional heat transport across a planet's surface. The thermal effect of clouds is accounted for by subtracting a correction term from the outgoing flux (Caldeira and Kasting, 1992). The time-dependent surface temperature distribution is described by a
combination of Legendre polynomials and a Fourier series that are solutions to a diffusion equation with periodic temporal boundary conditions in a spherical coordinate system.

The disk-averaged and diurnally averaged infrared flux for a prescribed viewing geometry is calculated along an entire orbit. As long as Eq. 1 is satisfied, diurnally averaging the infrared flux justifies the use of a single, average planetary albedo.

We consider only one set of Earth-like planetary parameters. Although such properties will undoubtedly vary among extrasolar planets, those planets with thermal properties similar to those of Earth will be the most compelling targets of investigation. The thermal inertia of the surface (8.34×10^7 J m^-2 K^-1) and heat diffusion coefficient (0.38 W m^-2 K^-1) were chosen so that, with an albedo (A = 0.3055), orbital semi-major axis (a = 1 AU), and eccentricity (e = 0.0167) of Earth, the model reproduces the meridional surface temperature distribution of Earth as well as the seasonal temperature variation at several latitudes (Gaidos and Williams, 2004).

The orbital properties (a, e, and i) of a real planet can be determined by imaging or astrometry, but the thermal properties of the planet may not be uniquely determined by independent means. We discuss this scenario in Section 7. Under the conditions of known orbital and thermal properties, the light curve is a function of the planet’s obliquity (\(\delta_0\)), the orbital longitude of inferior conjunction relative to the spring equinox (L_0), and the orbital longitude of the apastron (L_ap). If the orbit of the planet is nearly circular, then the longitude of apoastron L_ap (fixed here to 180°) is unimportant.

Ocean and atmospheric circulation and the thickness of an ocean’s mixed layer may differ for Earth-like planets with obliquities that are significantly larger than 23.5°. Thus, the actual light curves of such planets would differ from those calculated with Earth-like thermal properties. We examined this effect by comparing general circulation model (GCM) runs for \(\delta_0 = 85°\) to our EBM calculations (Fig. 1). The GCM used was the three-dimensional GENESIS 2 model (Williams and Pollard, 2003), and the calculations were performed with L_0 = 120°. The amplitude and general shape of the GCM light curves are nearly identical to those of the EBM. However, we find that the phase of the GCM light curves tend to lead those of the EBM by ~35°, with the greatest differences occurring when the geometry of the system is such that the poles of the planet are pointed toward the observer (e.g., high obliquity and high inclination). This is likely due to the inclusion of polar sea ice in the GCM.

The exact origin of the offset in phase is uncertain, but we suspect that it involves effects of seasonal changes in cloud cover, sea ice, or ocean circulation not included in the EBM. In Section 4, we show that artificially adjusting the phase of the EBM light curve (for i = 60°) to better match the GCM calculations only slightly increases the probability of satellite detection. In Section 5, we find that this phase lag does not affect the conclusion that an Earth-like planet with a lunar-like satellite produces light curves that resemble those of an isolated planet with high obliquity [i.e., one with large amplitude; see Gaidos and Williams (2004) for a comparison of light curves from Earth-like planets with high and low obliquities]. We are interested only in estimating the detectability of satellites and their gross effect on the interpretation of infrared light curves, rather than on detailed inferences about the climates of planets themselves; thus, we use the EBM to calculate light curves efficiently over a range of obliquity values.

Our formalism for calculating the outgoing infrared flux from a lunar-like satellite is also based upon the analysis in Gaidos and Williams (2004). In the absence of an atmosphere or oceans, the energy-balance equation governing the temperature (T) at a given point on the surface of a satellite with no latitudinal heat transfer is

\[
\frac{c}{A} \frac{\partial T}{\partial t} = S \cdot (1 - A) - I(T),
\]

where time is denoted by t, incident stellar flux by S, albedo by A, and outgoing infrared flux by I(T). S and I(T) are calculated as functions of longitude and latitude on the surface of the satellite, taking into account projection effects. To solve this equation analytically, three assumptions are made. First, c is assumed constant in time and across the satellite surface. Second, the temperature dependence of the outgoing infrared flux is approximated as a linearized blackbody:

\[
I(T) = I(T_0) \cdot (1 + 4(T - T_0)/T_0).
\]

This follows the approach of classical energy balance models (North et al., 1981). Finally, we assume tidally locked, synchronous rotation as is expected for large, collisionally formed satellites (Gladman et al., 1996; Canup and Agnor, 1998). These assumptions allow Fourier series solutions to Eq. 2:

\[
T(\theta, \ell) = T_0(\theta) + \sum_{n=1}^{N} \left[ a_n(\theta) \cos(n\ell) + b_n(\theta) \sin(n\ell) \right],
\]

where T_0 is the mean temperature for a given latitude \(\theta\), and \(\ell\) is the longitude on the surface of the satellite. N is set to 10.

**FIG. 1.** Calculated EBM (solid) and GCM (diamonds) light curves of a high-obliquity (\(\delta_0 = 85°\)) planet with Earth-like thermal properties. Light curves are shown for three values of inclination, L_0 = 120° (defined with respect to the vernal equinox) is used for both models. The two models are in close agreement regarding the amplitude of the planetary signal; however, the phase of the EBM calculations tends to lag by ~35°.
as numerical tests show that larger values do not significantly change the final light curve. Substitution of Eqs. 3 and 4 into Eq. 2 yields expressions for the Fourier coefficients:

\[ a_n(\theta) = \frac{\hat{a}_n(B + \alpha) - \hat{b}_n(B + \alpha)}{\sigma^2 + (B + \alpha)^2} \]  
\[ b_n(\theta) = \frac{\hat{a}_n\sigma - \hat{b}_n(B + \alpha)}{\sigma^2 + (B + \alpha)^2} \]

where \( \hat{a}_n, \hat{b}_n, B \) and \( \sigma \) are

\[ \hat{a}_n = \int_0^{2\pi} S(t, \theta) \cos(n\alpha) d\ell \]  
\[ \hat{b}_n = \int_0^{2\pi} S(t, \theta) \sin(n\alpha) d\ell \]  
\[ B = \frac{4I(T)}{T} \]  
\[ \sigma = \frac{g\kappa}{2} \sqrt{n} \]

The infrared emission from the surface is calculated with Eq. 3, and the total signal is determined by geometric projection of the hemisphere facing the observer.

For simplicity, we assume that the orbit of the satellite is coplanar with that of the planet’s orbit around the star and, because of synchronous rotation, the satellite has zero obliquity. Thus any variation in outgoing flux from the satellite is due to its finite heat capacity. The disk-averaged flux of the satellite is then independent of the location on its orbit around the planet and depends only on the geometric angle described by the star, satellite, and distant observer (Fig. 2). Variability in the satellite signal is due to its observed phase, which changes with the orbital phase of the planet. In Section 4, we consider satellites that differ in size (but not surface properties) from the Moon.

A satellite larger than the Moon will retain heat for a longer time and be more likely to have active volcanism. This could make the satellite darker, as in the case of the lunar mare. However, with an average albedo of 0.07, the Moon is already quite dark. Fresh basalt from active volcanism on the surface of a larger satellite would have little effect on its light curve.

3. Example Light Curves and Observations

Figure 2 illustrates how an Earth-Moon analogue would appear at five evenly spaced points in the system’s orbit. In Fig. 3, we have plotted the infrared light curves produced by this system. The bottom panel displays the disk-averaged flux, while the top shows light curves normalized to their respective means. This normalization (which is employed for all subsequent analysis) removes the radius of the planet as a degree of freedom in the model. The calculations were performed assuming an Earth “twin” (\( \delta = 23.45^\circ \)) with a satellite of radius, orbital period, and albedo equal to that of the Moon [0.273 Earth radii (\( R _ { \text{E} } \)), 29.5 days, and 0.073 respectively]. For these and all simulations, the coplanar orbits of the planet and satellite are inclined by 60\(^\circ\) with respect to the plane of the sky (the median value of an isotropic distribution). The dotted line in both panels is the contribution from the planet alone. The peak-to-peak amplitude of the satellite’s signal (dash-dots in the bottom panel) is 55 W m\(^{-2}\), whereas the planet’s flux alone varies by only 4 W m\(^{-2}\). Because the thermal inertia of the satellite is low, it displays a larger relative infrared flux variation than that of the planet (Eq. 1). However, because the satellite is smaller, the majority of the average flux originates from the planet.

The assignment of erroneous properties to a planet with an undetected satellite is illustrated in the top panel of Fig. 3, where the dashed line is the best-fit planet-only model to the
IR LIGHT CURVES OF PLANETS WITH LARGE SATELLITES

4. Satellite Detection Limits

We determine the minimum size of a Moon-like satellite that can be detected around an Earth-like planet whose gross thermal properties are outlined in Section 2. We presume that the inclination of the planet’s orbit with respect to the plane of the sky is independently measured by astrometry and use a single value of 60°. For these calculations, the orbital and thermal parameters of the planet and the orbital period, albedo, and thermal inertia of the satellite (assumed to be equal to that of the Moon) are held fixed, while \( \delta_0 \), \( L_0 \), and the satellite radius \( R_s \) are allowed to vary. With the exception of cases with extremely high planetary obliquity, where most of the planetary signal is at twice the orbital period (Gaidos and Williams, 2004), the signal from the planet and satellite will have the same period. There are then three unknowns \( (\delta_0, L_0, R_s) \) but only two measurable quantities: the amplitude and phase of the orbital signal. Thus, it is not possible to disentangle the planetary and satellite signals uniquely. Instead, we define a satellite “detection” as the case where the observations cannot be accounted for by a planet-only model.

Our detection analysis is as follows: We generate an array of planetary light curves over the full ranges of \( \delta_0 [0–90°] \) and \( L_0 [0–360°] \). The satellite light curve for a given \( R_s \) is calculated and added to each planet light curve in the array. Each total light curve is sampled at \( N \) specified points according to either of the observing schemes described in Section 3. Random noise with a given root mean square is added to these measurements. We then perform an exhaustive search of planet-only light curves to find the minimum \( \chi^2 \) fit to the measurements. The analysis is repeated for different values of \( R_s \). We interpret the confidence level \( C \) associated with the value of \( \chi^2 \) and the number of degrees of freedom as the probability that the deviation from the planet-only model is due to the presence of a satellite. This is because \( 1 – C \) is the probability that measurements of the light curve of the planet alone would result in a fit with a \( \chi^2 \) larger than the observed value, i.e., a false positive. We set the effective number of degrees of freedom to the minimum \( \chi^2 \) value associated with a best fit to \( N \) observations of the planet-only light curve. Although this minimum \( \chi^2 \) value is sensitive to the random noise characteristics of a given sampling, we find that a more robust calculation of the true \( \chi^2 \) minimum \((i.e., \text{averaging over a large number of random noise patterns})\) produces results that are in close agreement with this single noise characteristic approximation. Our minimum \( \chi^2 \) approximation produces an increase of nearly an order of magnitude in computational efficiency over the robust method.
We average $C$ over $L_0$, which cannot be independently determined for any system but will have a uniform probability distribution. In addition, $C$ is averaged over all possible phases of the measurement scenarios, i.e., the longitudes at which the planet is observed are shifted by 2-degree increments over the orbital phase range $2\pi/N$. This produces an average probability of detection ($C_i$) for a given $R_s$ and $d_0$. The planet’s obliquity cannot be independently determined from the light curve of the planet + satellite, nor can it be assumed to have an isotropic distribution (Atobe and Ida, 2007). In Figures 4 and 5, we have plotted $C_i$ vs. obliquity for several values of satellite radius (in units of planetary radius). For an Earth-sized planet, this range of radii corresponds to Vesta- to Mars-sized bodies. The two figures correspond to the “confirmation” (5 evenly spaced observations at $S/N = 10$) and “characterization” (14 observations at $S/N = 20$ distributed around 50% of the planet’s orbit) observation scenarios described in Section 3. As the radius of the satellite increases, the observations become increasingly inconsistent with a planet-only light curve; thus the probability of satellite detection increases. For satellites smaller than 0.33 planetary radii, the probability of detection is lower in the “characterization” observing scheme. This is an effect of the observations being distributed around only 50% of the orbit. The incomplete phase sampling of this scheme does not capture the peak of the satellite flux, which occurs at the longitude of superior conjunction. However, for large satellites ($R_s \geq 0.33$ planetary radii), the amplitude of the net light curve becomes so great that the satellite is detected even without complete phase coverage. The scatter in these probability curves is due to the stochastic noise added to each of the sample measurements. For both observation schemes ($C$) is very weakly dependent on obliquity. These results show that a Moon-like satellite (0.27 $R_p$) would only be detectable with $\sim 30\%$ confidence by either observation scheme. For the “confirmation” and “characterization” observing schemes, a satellite would have to be 0.5 and 0.38 planetary radii, respectively, to be detected with 90% confidence. This corresponds to approximately Mars-sized satellites in orbit around an Earth.

In Fig. 6, we consider how these results would change if a full three-dimensional climate model were used to generate the planetary light curves. As previously stated, our EBM produces light curves that lag by $\sim 35^\circ$ relative to those of the GENESIS 2 GCM for obliquities of 23.5$^\circ$ and 85$^\circ$. To mimic the results of the GCM, we offset the phase of the EBM light curves by $35^\circ$ and repeat the analysis of Fig. 5. It would be computationally prohibitive to generate GCM light curves for the full range of obliquities that are included in this analysis; thus, we approximate the GCM by applying this offset. We find that the probability of detection actually increases.

**FIG. 4.** The $L_0$ averaged probability of satellite detection as a function of planetary obliquity for a range of satellite radii (0.16, 0.22, 0.27, 0.33, 0.38, and 0.44 planetary radii). The radius of the Moon is 0.27 $R_p$. These simulations were performed with five evenly spaced observations and a $S/N$ of 10. As the radius of the satellite increases, it becomes increasingly difficult to explain the sample measurements with a planet-only light curve; thus the probability of detection increases.

**FIG. 5.** Similar to Fig. 4, except for the “characterization” observing scheme: 14 sample points with a $S/N$ of 20, distributed around 50% of the planet’s orbit. Although the $S/N$ is higher than the observations of Fig. 4, the distribution of sample points around only 50% of the orbit makes it difficult to detect satellites of small radii ($\leq 0.33$ planetary radii).

**FIG. 6.** Similar to Fig. 5, except that a $35^\circ$ phase shift has been applied to all EBM planetary light curves so that they agree with the GENESIS 2 GCM. With use of these pseudo-GCM light curves, the detection probability actually increases relative to the EBM case (Fig. 5). This suggests that the EBM places a lower limit on the probability of satellite detection.
IR LIGHT CURVES OF PLANETS WITH LARGE SATELLITES

slightly with the phase-adjusted pseudo-GCM light curves (Fig. 6). Thus, we conclude that our EBM results are conservative estimates for the probability of satellite detection.

5. Errors Introduced by an Undetected Satellite

As we showed in Fig. 3, the application of planet-only models to a set of observations can result in mischaracterization of the Earth-like planet if a large satellite is present. Even if the gross thermal properties of the planet have been independently established, this will still produce erroneous values of \( \delta_0 \) and \( L_0 \). We describe this effect by recording the “true” \((\delta_0, L_0)\) pair for a given planet + satellite light curve and the \((\delta_0, L_0)\) pair of the best-fit planet-only light curve as determined by a \( \chi^2 \) analysis. In some instances, a planet + satellite light curve can be fit with equally low \( \chi^2 \) by more than one planet-only light curve. For these cases, we choose the \((\delta_0, L_0)\) pairs that are closest to the true value. In Fig. 7, we have plotted the direction and proportional magnitude of the error introduced by satellite confusion (the length of the vectors have been reduced for clarity). These simulations were run for an Earth-like planet with a satellite of radius \( 0.07 \) that produces planet-only light curves with large amplitudes that can reasonably fit a planet + satellite system. Adjusting for the phase difference between the EBM and the GCM does not significantly impact our conclusions.

6. The Effect of Clouds

Clouds play an important role in the energy balance and climate of Earth by reflecting sunlight and scattering and trapping long-wavelength radiation; they would presumably do so for Earth-like extrasolar planets as well. Although clouds represent a mean 20 W m\(^{-2}\) (8%) gain in radiation for Earth (Hartmann, 1994), we are concerned here only with their seasonal affect on the energy budget and disk-integrated outgoing radiation. These seasonal effects will be most prominent when one hemisphere is presented to the observer. On Earth, low clouds (stratocumulus) produce a decrease in net radiation, while high clouds (cirrus) produce an increase (Hartmann, 1994).

We estimate the thermal effect of seasonal variability in stratocumulus clouds on the light curve of an Earth twin. We assume that these low-altitude clouds radiate at the same temperature as a clear atmosphere and surface, i.e., they produce no additional greenhouse effect. We use a cloud albedo of 0.7 (Hartmann, 1994). Comiso and Stock (2001) estimated variation in cloud cover over the open ocean around Antarctica to vary by only \( \pm 1\% \) around a mean of 91%. Seasonal variation of \( \pm 10\% \) around a mean of 80% was observed over the North Atlantic (Massons et al., 1998). We adopt a 20% seasonal variation in the mean as a reasonable bracketing value. To produce the global mean Earth albedo of 0.31, a dark ocean \((A = 0.07)\) must be covered with 37% clouds. Although the average cloud cover on Earth is \( \sim 60\% \), only half those are low-altitude stratocumulus (Minnis et al., 2002), a value in reasonable agreement with the calculated fraction of 37%. A \( \pm 20\% \) fluctuation in the mean coverage produces an albedo variation of 0.047. We assume that the albedo variation is uniformly distributed over each (northem/southern) hemisphere and that it varies sinusoidally in phase with the summer solstice. (This obviously produces a nonphysical discontinuity at the equator, which is unimportant for the purposes of estimating the magnitude of the effect of clouds). We examined the light curves of two cases: one in which an Earth twin is observed at a moderate inclination \((i = 60\degree)\) and the other in which a high-obliquity Earth is observed on an edge-on orbit \((i = 90\degree)\) so that one hemisphere is seen nearly pole-on (results not shown). In both cases, the annual mean of the disk-averaged flux is slightly lower in the presence of low-altitude clouds, but the amplitude and phase of the variation is essentially unchanged. Of course, pathological deviations from terrestrial patterns of cloudiness are possible on planets not quite like Earth, but we have already shown with a GCM model (that includes parameterized cloudiness) that, in at least the high-obliquity regime, our conclusions are not significantly impacted.

For an Earth-like planet, high-altitude clouds will cause a greenhouse effect whose net effect is to offset any decrease in infrared emission caused by their high albedo. Variation in the fraction of high-altitude cloud cover on timescales of less than \( \sim 1 \) day will be averaged over, during typical integrations. We argue that variation in high cloud cover over longer timescales will be insignificant compared to estimated
noise characteristics for a typical observation. High-altitude clouds with a temperature of 210 K would emit ~40% less radiation than the surface. With typical high cloud-cover fractions of ~30% (Minnis et al., 2002) and again assuming ±20% fluctuations in coverage, we calculate that fluctuations in outgoing infrared flux due to high cloud variability will be on the order of a few percent (40% of surface flux × 30% coverage × 20% variability), which would be unresolved by observations with an optimistic S/N of 20. In a more extreme case (e.g., larger variability, greater mean surface coverage, or lower emitting temperatures), the variability in a light curve due to high-altitude clouds will act to further confuse its interpretation.

7. Discussion

The simulations presented here show that time-series infrared photometry by a TPF- or Darwin-like observatory would reveal only the very largest lunarlike satellites (Mars-sized) around Earth-analog planets, and then only if these Earth-like properties, i.e., the presence of oceans or a substantial atmosphere, or both, have been established by independent means, e.g., spectroscopy or optical photometry. This conclusion holds for a wide range of planetary obliquity (Figs. 4, 5, 6), assuming that the approximations of the EBM do not grossly misrepresent the infrared light curve of a high-obliquity Earth-like planet (Fig. 1).

When interpreting infrared light curves, the presence of an undetected lunarlike satellite can suggest erroneous values of planetary obliquity and longitude of inferior conjunction. In the case of a planet with high thermal inertia, inferred values of $\delta_0$ near 90° and $L_0$ values within 35° of 90° or 270° may indicate the presence of a lunarlike satellite. This result is based on the assumption that the satellite and planetary orbits are coplanar, which may not be the case for high-obliquity planets. Kinoshita (1993) showed that the orbit of a satellite will stay in the equatorial plane of its host planet if the secular rate of change of the planet’s obliquity is slower than the precessional speed of the satellite orbital plane. Thus, satellites around planets that experienced rapid changes in obliquity [possibly by collisions as in the case of Uranus (Parisi and Brunini, 1997)] would stay in their coplanar orbits.

If a satellite’s orbit is non-coplanar, then its rotation axis will be tilted with respect to the plane of the planet’s orbit. This effectively causes a non-zero obliquity for the satellite, which will modify the amplitude of the satellite’s light curve but will not change its period. If this non-coplanar orbit precesses, the signal will change over a timescale of many orbital periods.

If the thermal properties of a planet are not independently established via spectroscopy (Des Marais et al., 2002), visible-wavelength detection of glint from an ocean, or significant polarization of visible reflectance (McCullough, 2008; Williams and Gaodo, 2008), then the flux from an unresolved lunarlike satellite can induce serious errors. If the measurements are modeled with the several free parameters (e.g., $\delta_0$, $L_0$, $A$, $c$ and efficiency of meridional heat transport), then a set of planet + satellite measurements can be satisfactorily fit by a planet-only light curve. For instance, the peak-to-peak light curve amplitude from a system with a large, unresolved lunarlike satellite around an Earth-analog planet can be fit by a planet with low thermal inertia and drastically different $\delta_0$ and $L_0$, which implies a planet more akin to Mars than Earth. Such an erroneous inference would impact the determination of the frequency of habitable planets. This reinforces the need for multiple wavelength observations, including spectroscopy and photometry to disambiguate the characterization of extrasolar terrestrial planets (Beichman et al., 2006; Traub et al., 2006).

Where, optimistically, the thermal properties of a planet are known and its satellite is Mars sized, the existence of a satellite may be inferred from infrared data. Such a discovery would provide information about the collisional and kinematic evolution of the parent planet. In addition, a large satellite could be a potential indicator of habitability, as the presence of the Moon is known to stabilize the obliquity and climate of Earth (Laskar et al., 1993).
