

IDENTIFICATION AND QUANTIFICATION OF SUBMARINE GROUNDWATER
DISCHARGE IN THE HAWAIIAN ISLANDS

DISSERTATION SUBMITTED TO THE GRADUATE DIVISION OF THE
UNIVERSITY OF HAWAII AT MĀNOA IN PARTIAL FULFILLMENT OF THE
REQUIREMENTS FOR THE DEGREE OF

DOCTOR OF PHILOSOPHY

IN

GEOLOGY AND GEOPHYSICS

AUGUST 2012

By

Jacque L. Kelly

Dissertation Committee:

Craig Glenn, Chairperson

Paul Lucey

Henrieta Dulaiova

Brian Popp

Aly El-Kadi

Francis Sansone

Keywords: Submarine groundwater discharge, Oahu, thermal infrared, radon, dissolved
inorganic nutrients, Pearl Harbor

ACKNOWLEDGEMENTS

I thank my advisor, Craig Glenn, for helping me see my dissertation project from the very beginning to very end. Paul Lucey has been instrumental for teaching me the finer points of thermal infrared image processing. Henrieta Dulaiova is graciously thanked for many hours of radon modeling input and field support. Brian Popp freely shared his knowledge of working with stable isotopes. I thank Aly El-Kadi and Frank Sansone for valuable discussion throughout the duration of this research project. The United States Navy provided equipment, personnel support, and access to Pearl Harbor. I thank the Harbor Master, the Port Operations Master, the US Navy dive team, William Simonson, and Mary Donohue for making the field work in Pearl Harbor possible. Mark Wood and Mike Borden assisted with aerial TIR data collection. Elizabeth Gier helped with the nitrate isotope analyses. Sally Beaver provided access to the Kaloko-Honokohau National Historical Park observation wells as well as the pump used to obtain the water in those wells. Malia Lebar at Puuhonua o Honaunau provided access to the anchialine pool. Ricky Peterson, Amanda Peterson, William Burnett, and Carrie Plath assisted with sample collection on the island of Hawaii. I thank Kayla Holleman, Christine Waters, Joseph Fackrell, Borja Pardo, Kimberly Mayfield, Joseph Kennedy, George Bugarian, and Lerma Gaimo for multiple hours of assistance and discussion. I am gratefully appreciative to numerous volunteers from the University of Hawai‘i at Mānoa who helped deploy and retrieve thermistors. The Hawaiian Electric Company's Waiiau Power Plant, and the Board of Water Supply, City and County of Honolulu provided access and personnel for water sampling on Oahu. The Hawaii Department of Water Supply graciously provided access to their drinking water wells for sample collection on the island of Hawaii. Appreciation is given to many other landowners who permitted access to their water wells and ponds for sample collection.

Primary financial support for this project is by a grant to C.R. Glenn from the National Oceanic and Atmospheric Administration (NOAA), Project R/HE-2, which is sponsored by the University of Hawai‘i Sea Grant College Program, School of Ocean and Earth Science and Technology (SOEST), under Institutional Grant No. #NA09OAR4170060 from NOAA, Department of Commerce. Funding for this project was also from a National Science Foundation Collaborative Research Grant, OCE04-

51379 to C.R.Glenn, and NSF Hawai‘i EPSCoR Program through National Science Foundation under award number EPS-0903833. Additional funding was supplied from the Geological Society of America Stearns Fellowship to J.L. Kelly, a University of Hawai‘i Department of Geology and Geophysics Harold T. Stearns Fellowship to J.L. Kelly, three University of Hawai‘i Department of Geology and Geophysics William T. Coulbourn Fellowships to J.L. Kelly, and a University of Hawai‘i at Mānoa Graduate Student Organization Travel Grant to J.L. Kelly. The views expressed herein are those of the authors and do not necessarily reflect the views of any agencies listed.

I thank Tom Fitz and Bruce Goetz for introducing me to Geology. Their continuous support and encouragement has been instrumental to my decision to study Geology.

Finally, infinite thanks are due to my amazing husband and wonderful son. I also thank my family and friends, especially Jimi and Terri. Thank you for your love and support.

ABSTRACT

Submarine groundwater discharge (SGD) is a fundamental pathway for nutrient and contaminant entry to the world's coastal zones from terrestrial aquifers. The distribution and scale of SGD vary spatially and temporally, necessitating use of multiple methodologies for its study. High-resolution aerial thermal infrared (TIR) remote sensing was employed to map the distribution of cold SGD around much of Oahu, Hawaii, and a dual infrared thermography and in situ tracer (^{222}Rn , temperature, salinity, and dissolved inorganic nutrient) study in Pearl Harbor was conducted to determine locations and fluxes of groundwater discharge to the harbor. Surface water surveys of the natural tracer ^{222}Rn in Pearl Harbor confirmed point source and diffuse seepage areas identified in SST maps. Conservative estimates of groundwater fluxes derived from ^{222}Rn inventories of surface water indicate that between 119,400 and 322,030 m^3/d of groundwater enters the harbor along its shoreline. Recently discharged groundwater contributes at least 51,600 mol/d of nitrate, 4,500 mol/d of phosphate, and 835,000 mol/d of silica to the harbor. Isotopic analyses of dissolved nitrate suggest that multiple water sources exist in the harbor and that these sources mix within the aquifer.

Chlorofluorocarbon groundwater apparent ages in Kona Hawaii were investigated to determine groundwater residence times and potential implications of the residence times on discharging groundwater. A single water-source model indicates that groundwater recharged four supply wells during the mid-1960s and mid-1970s. Recharge occurred between the mid-1970s and mid-1980s for several coastal wells and ponds using the same model. Alternately, a simple binary mixing model, with one water source recharged prior to 1940 (young water) and the other after 1940 (old water), indicates recharge of the young water fraction from between the mid-1970s to mid-1980s for several wells and coastal ponds. Water supply wells contain greater proportions of relatively old groundwater than coastal wells and ponds, consistent with sampling depths, complex aquifer geometries, and varied flow networks that cause mixing of old water with younger water within the aquifers. Furthermore, CFCs may be used to identify water from different aquifers.

CHAPTER 1. INTRODUCTION

Submarine Groundwater Discharge

Submarine groundwater discharge (SGD) is a global, naturally occurring process that happens wherever coastal aquifers are in direct communication with the sea. SGD is typically defined as any and all flow of water across the sea floor regardless of fluid composition or driving force (Burnett et al., 2003). The definition of SGD includes water circulation through continental shelf sediments, but excludes deep-sea hydrothermal circulation, deep fluid expulsion at convergent margins, and density-driven cold seeps on continental slopes (Burnett et al., 2006).

Submarine groundwater discharge is an important component of the hydrological cycle. The Atlantic Ocean, for example, receives similar volumes of SGD and riverine inputs (Moore et al., 2008). In the Hawaiian Islands, Garrison et al. (2003) found a similar relationship of equal fluxes of SGD and surface runoff to Kahana Bay on Oahu. In addition, although the flux of SGD to coastal ecosystems may be less than surface water inputs, SGD's dissolved nutrient concentrations are often much larger than surface water counterparts. An excellent example of this disparity was demonstrated by Garrison et al. (2003) for Kahana Bay, where estimates of total dissolved phosphorus fluxes and total dissolved nitrogen fluxes from SGD were 500 and 200 times greater, respectively, than fluxes from surface runoff. Similar relationships have been found in numerous areas, including South Carolina (Krest et al., 2000) and Thailand (Burnett et al., 2007). SGD can, therefore, impact coastal ecosystems leading to eutrophication (Paerl, 1997; Bowen et al., 2007), harmful algal blooms (Paerl, 1997; Hu et al., 2006; Lee and Kim, 2007), and shifts in the dominant flora and fauna of coastal waters (Dollar and Atkinson, 1992; Miller and Ullman, 2004).

Since SGD occurs at a variety of scales, is spatially and temporally variable, and may flow through easily identifiable point-sources or as more discrete, diffuse flows, a variety of methods are customarily employed to effectively study this common coastal zone process. Burnett et al. (2006) provides a comprehensive overview of different measurement techniques, including seepage meters, piezometers, radiochemical tracers, temperature, and salinity. I have primarily employed temperature, salinity, and the radiochemical tracer radon-222 (^{222}Rn) to study SGD.

Temperature and salinity are two of the easiest tracers of SGD to measure. Temperature can be utilized to study SGD in areas where the temperature of discharging water contrasts with that of receiving water. Since SGD typically contains a fresh groundwater component, the salinity of the discharging water will be fresher than seawater. Temperature and salinity are usually measured concurrently during in situ field work via boat or shoreline surveys.

Thermal infrared (TIR) remote sensing is another method used to detect SGD. The TIR technique utilizes the typically buoyant nature of groundwater discharge relative to estuary or ocean water. The method is used to determine temperature differences between discharging groundwater and coastal water. TIR data can be obtained from satellite missions (e.g. Varma et al., 2010; Wilson and Rocha, 2012) or aerial missions (e.g. Miller and Ullman, 2004; Mulligan and Charette, 2006; Johnson et al., 2008) to study SGD. Satellite data are relatively inexpensive for the end-user, but typically cannot resolve SGD on the smaller scales at which it is normally observed. Aerial surveys require specialized equipment and aircraft time, but do provide information about SGD on the scales at which it is commonly observed. However, the TIR technique only senses the surface skin of the water column. It does not provide information about mixing that occurs within the water-column or groundwater discharge from sediment/water interface that does not float to the water's surface, for example.

^{222}Rn is a natural radiochemical tracer of groundwater discharge (e.g. Dulaiova et al., 2005; Burnett et al., 2006). ^{222}Rn is radioactive-conservative and is enriched in groundwater aquifers relative to ocean water due to the natural occurrence of ^{238}U in basalt and sedimentary rocks. ^{238}U is a parent isotope of ^{222}Rn . This enrichment of ^{222}Rn in groundwater results in a large concentration gradient between the discharging groundwater and the receiving water, making identification of groundwater discharge based on elevated ^{222}Rn activities possible. A disadvantage of using ^{222}Rn is that all non-groundwater sources and sinks must be evaluated (Burnett et al., 2006).

Field Sites

I primarily investigated two field sites for my in situ research. One field site was Pearl Harbor, Hawaii on the island of Oahu. The other field site was the Kona Coast, on the west side of the island of Hawaii.

Pearl Harbor is the largest estuary in the Hawaiian Islands. It also has the largest freshwater spring complex in the Hawaiian Islands. Pearl Harbor represents a drowned river system that has been successively flooded and drained as a result of past sea-level changes (Stearns, 1985). During lower sea-level stands, fairly impermeable sedimentary rocks were deposited over much of Pearl Harbor's coastal plain and valley mouth areas (Stearns and Vaksvik, 1935). The sedimentary rocks were deposited on top of the volcanic rocks that contain the island's primary drinking water aquifer. The main source of groundwater to the Pearl Harbor area originates from rainfall over the Koolau Mountains on the north and east sides of the harbor. Smaller amounts of water originate from the Waianae Mountains to the west of the harbor (Hufen et al., 1980). This groundwater converges in the basaltic aquifer along a narrow zone between the inland edge of the sedimentary rocks and ~6 m above sea level (Stearns and Vaksvik, 1935; Visher and Mink, 1964). The confining sedimentary rock pressurizes the upper part of the volcanic-rock aquifer and produces numerous subaerial springs. Less voluminous subaerial and submarine springs flow from more seaward areas of the sedimentary rock (Lau, 1962; Visher and Mink, 1964). Hunt (1996) also speculated that groundwater discharge occurs as diffuse leakage through the sedimentary rocks and in areas where the confining sedimentary rocks are absent or scant. Sources of water to Pearl Harbor include stream flow and runoff from precipitation, spring-fed streams, subaerial springs near the estuary, submarine springs, and diffuse flow.

The Kona Coast is located on the dry, western side of the island of Hawaii. Hawaii Island is composed of numerous lava flows with variable thicknesses and composition. The permeability of the rocks is heterogeneous, but is high overall (Stearns and MacDonald, 1946). The coastal area receives between 500 and 1000 mm of rain per year. This contrasts to the inland, and upslope areas of the coast that receive >2000 mm of rain per year. Recharged water flows toward the coast through volcanic rock aquifers and eventually discharges to the coast as submarine groundwater discharge. There are no perennial streams in the area, so submarine groundwater discharge is the only source of freshwater to the area's coastal zones.

Research Objectives

My research has primarily been focused on three objectives related to the study of SGD. My first objective was to fully develop a method to locate SGD on regional scales. My second objective was to quantify SGD that I identified by completing my first objective. My final objective was to understand how groundwater end-member sources, mixing, and nutrient transformations impact SGD. The research presented within primarily utilizes TIR remote sensing and ^{222}Rn as a tracer of SGD.

Previous studies of SGD have demonstrated that TIR remote sensing can be used to identify SGD (e.g. Miller and Ullman, 2004; Mulligan and Charette, 2006; Johnson et al., 2008), but very few studies have employed the technique at regional scales (e.g. Johnson et al., 2008). The aerial TIR technique has remained relatively inaccessible to most researchers because a thorough description of the necessary equipment and methods has been lacking. Furthermore, the cost to obtain such data through outside vendors is typically prohibitive (\$100K or higher per survey).

My primary hypothesis for my first research objective was that aerial TIR remote sensing would be a reliable technique to detect SGD on the scales it is commonly observed. With that in mind, I developed a methodology for aerial TIR remote sensing that includes data collection, post-flight data processing, and image interpretation. To test my hypothesis, I employed aerial TIR remote sensing to detect SGD on a regional scale (the island of Oahu, Hawaii). I further validated SGD detections from the aerial TIR imagery by conducting in situ field work in Pearl Harbor using commonly-used and well-established in situ SGD tracers (temperature, salinity, and ^{222}Rn).

My second objective was to utilize the aerial TIR imagery to plan in situ field work to quantify SGD in Pearl Harbor, Hawaii. One hypothesis for this research was that the aerial TIR surveys and in situ ^{222}Rn measurements would identify similar areas of groundwater discharge. To determine groundwater fluxes to the harbor, I employed ^{222}Rn mass balance techniques (e.g. Dulaiova et al., 2005, 2010). I collected ^{222}Rn data from stationary time-series platforms, surface-water surveys of ^{222}Rn , and water-column surveys of ^{222}Rn .

I also characterized nutrient concentrations in groundwater end-members to develop nutrient budgets for the harbor. I conducted this research to partially fulfill the

third objective of my dissertation. To understand nitrogen transformations along flow paths, I also employed the “denitrifier” method (Sigman et al., 2001; Casciotti et al., 2002) to determine nitrogen and oxygen isotopic compositions of nitrate dissolved in groundwater.

SGD assessment necessitates a thorough understanding of groundwater influences upland of discharge sites as well as an understanding of the changes groundwater undergoes as it travels through aquifers and discharges to coastal waters. In order to understand how groundwater end-member sources and evolution impact SGD, one must first know about aquifer residence times. The hypothesis for my third objective was that chlorofluorocarbons (CFCs) could be used in the fairly pristine environment on the Kona Coast to determine apparent groundwater ages of water in both high-level and basal aquifers. Furthermore, once a recharge date was known with some certainty, groundwater sources and mixing could be evaluated. Potential then existed for inferences about how changes in land-use and climatic patterns may have impacted recharging aquifers and how those patterns may impact the discharging groundwater, and coastal ecosystems receiving the discharge. I would have loved to conduct this research in the Pearl Harbor area; however, previous research by Hunt (2004) demonstrated that CFCs were unable to determine apparent groundwater ages for the area because of recent recharge related to agricultural practices.

Significance of Work

Since SGD is spatially and temporally variable, and nearly invisible in plain (visible) light, locating SGD can be quite challenging. I have devised an aerial TIR remote sensing technique that quickly and accurately locates point-source and non-point-source SGD inputs on a regional scale by using temperature differences between discharging and receiving waters. Once airborne, approximately 40 km of coastline can be mapped per hour with this technique. Aerial TIR remote sensing, therefore, provides the ability to regionally assess SGD on the scale it is normally observed in a few hours of flight time. Post flight data processing is involved, but a well-trained person can process one flight line, calculate surface plume areas, and make a publication quality sea-surface temperature (SST) map in about twelve hours. This is typically the same amount of time

that it would take a well-trained person to process in situ measurements of one ^{222}Rn time-series platform or one ^{222}Rn survey for locating SGD.

Aerial TIR imagery is usually utilized qualitatively to study SGD. I have confirmed that SST maps are also quantitative tools that can be used to calculate surface plume areas. Furthermore, I have confirmed that surface plume areas identified in the infrared imagery do correlate to measured SGD fluxes. This correlation provides a way to estimate total groundwater discharge to a field area by measuring fluxes for only a few SGD plumes.

In situ assessment is crucial for confirming SGD identified in SST maps. I demonstrate that SST maps do correlate to SGD locations through field measurements conducted in Pearl Harbor, Hawaii. Pearl Harbor is the largest estuary in the Hawaiian Islands and has the largest spring complex in the Hawaiian Islands. Quantifying groundwater inputs to the harbor, therefore, also has broader significance to the scientific community than just confirming that aerial TIR remote sensing reliably and accurately detects SGD. One particularly significant aspect of my research in Pearl Harbor involves estimating groundwater and dissolved nutrient fluxes to the harbor on a segment-by-segment of coastline basis. This technique utilizes ^{222}Rn mass balance models and provides flux estimates in units of volume of water per length of shoreline per unit of time. These units allow for easy comparison of groundwater discharges and nutrient fluxes throughout the harbor, as well as with other locations around the world.

SGD, by definition, excludes all subaerial inputs of groundwater to a field area. The numerous subaerial spring sources to Pearl Harbor do contribute recently discharged groundwater to the estuary. In the strictest sense, we measured SGD to Pearl Harbor through completion of my second objective. I do, however, recognize the importance of the subaerial springs to the overall water (and nutrient) budget for the harbor. I also recognize that the ^{222}Rn tracer will detect non-degassed water from the subaerial springs, but will not detect degassed water from the subaerial springs. The flux estimates of SGD by ^{222}Rn mass balance will therefore include fractions of subaerial spring discharge that have not completely degassed ^{222}Rn , before entering the estuary. Unfortunately, ^{222}Rn cannot distinguish true SGD from subaerial spring discharge in these situations. I have therefore estimated fluxes of freshwater discharge from the subaerial springs using a

salinity balance model. I also estimate subaerial spring fluxes using linear correlations between spring discharge rates and water-head in a nearby water supply well (Oki, 1998). This research, as a whole, does provide the most up-to-date assessment of Pearl Harbor's groundwater resources. Furthermore, our flux estimates include diffuse seepage to the harbor, which has not been previously measured.

Nitrogen isotopic studies of macroalgae have been used in the Hawaiian Islands to study nitrogen sources to coastal waters (e.g. Derse et al., 2007; Dailer et al., 2010, 2012). Aside from research by Hunt (2007) and Hunt and Rosa (2009), use of isotopic analyses of dissolved nitrate in groundwater to study nutrient sources and cycling has been underutilized in the Hawaiian Islands. I have measured the combined nitrogen and oxygen isotopic composition of dissolved nitrate from water supply wells, coastal springs, and estuary waters in the Pearl Harbor area. To my knowledge, this is the first study in Hawaii to use stable isotope analyses of dissolved nitrate in areas that are not directly impacted by waste-water injection.

My combined use of oxygen and hydrogen isotopic analyses of groundwater, $\delta^{18}\text{O}$ /altitude gradients, and well-established lapse rates has provided an integrated way to establish recharge trajectories for water samples. An integrated approach can easily be applied to other areas in the Hawaiian Islands with steep elevation gradients. I have also shown that CFCs can be successfully applied to more pristine areas in the Hawaiian Islands and can potentially be used to determine if a water sample originated from high-level or basal aquifers. The broader implications of this research include (1) the ability to assess anthropogenic inputs along water flow paths, (2) the ability to infer how land-use changes may impact groundwater resources, including those that discharge to the sea, and (3) the ability to evaluate how changes in climatic patterns may impact groundwater resources, including those that discharge to the sea.

Dissertation Organization

Since SGD is cold relative to seawater in the Hawaiian Islands, temperature is a tracer that distinguishes SGD from coastal waters. One very effective way to determine the spatial distribution of SGD on a regional scale is to generate SST maps using TIR remote sensing. I choose airborne mapping missions because they provide much higher spatial resolution (0.5 to 3.2 m) compared to satellite data (60 m). This technique

allowed me to collect SST data from approximately 40 km of coastline per hour with a temperature accuracy of 0.5°C and a precision of 0.1°C. *Chapter 2* presents a complete methodology for data collection, post-flight data processing, and image interpretation of infrared data. Specific examples are given from the islands of Oahu, Hawaii, and Maui. Since the material presented in *Chapter 2* is primarily methods, I have written the chapter in the Limnology and Oceanography Methods style.

^{222}Rn , a geochemical tracer of SGD, is generated from the decay of uranium-series isotopes naturally present in the volcanic and sedimentary rocks of the Islands. Once produced, ^{222}Rn can dissolve into the groundwater. As a result, groundwater becomes enriched in ^{222}Rn relative to seawater. Groundwater discharge therefore generates concentration gradients, which are detectable by surface-water ^{222}Rn surveys, ^{222}Rn surveys of the water column, and stationary time-series ^{222}Rn measurements. *Chapter 3* discusses the combined use of aerial thermal infrared remote sensing and ^{222}Rn measurements in Pearl Harbor, Hawaii. The aerial TIR survey and the ^{222}Rn survey are independent techniques and operate at different scales (3.2 m for thermal infrared and 1-100 m for ^{222}Rn surveys). Both methods identified similar groundwater discharge areas. Groundwater discharge fluxes for Pearl Harbor are also presented in *Chapter 3*.

Of particular concern to ecosystems health and management is nutrient loading, especially where anthropogenic influences impact nutrient loads entering coastal zones. SGD is a natural pathway for transportation of dissolved nutrients into coastal areas. In the Hawaiian Islands, groundwater is naturally enriched in dissolved nutrients compared to the oligotrophic waters surrounding the Islands. *Chapter 4* presents dissolved nitrate, dissolved phosphate, and dissolved silica nutrient budgets for Pearl Harbor. Potential sources of dissolved nitrate within the groundwaters entering the harbor and processes modifying the dissolved nitrate as groundwater flows from mountainous recharge areas to coastal discharge zones are also addressed.

Understanding groundwater nutrient evolution, recharge altitudes, probable recharge areas, and flow paths is important for assessing how groundwater discharge may vary through time. Such assessments require knowledge of aquifer residence times. The chlorofluorocarbon technique is a well-established method for assessing apparent groundwater ages on a 60-year time scale. *Chapter 5* presents apparent groundwater ages,

recharge altitudes, and probable recharge areas for multiple aquifers located near Kona, Hawaii.

Chapter 6 discusses the major conclusions of my research. I also present ideas for future research that expand upon what I have presented within my dissertation.

I have collected aerial TIR imagery from much of the island of Oahu. I present this imagery in *Appendix 1*. The imagery is organized in panels starting at Hanauma Bay that move clock-wise around the island ending at Kawela Bay. I was unable to map windward Oahu from Kaneohe Bay to the east side of Hanauma Bay due to persistent cloud-cover. The temperature scales in each SST map vary between panels to maximize contrast of features located within each panel. All panels are, however, shown at the same map scale (1:25,000) so features in different panels may be easily compared.

A large amount of in situ data from a variety of scientific apparatuses has been collected for my dissertation. I have compiled all of this data in *Appendix 2*.

CHAPTER 2. HIGH-RESOLUTION AERIAL INFRARED MAPPING OF GROUNDWATER DISCHARGE TO THE COASTAL OCEAN

Introduction

Submarine groundwater discharge (SGD) is a global, naturally occurring process that happens wherever coastal aquifers are in direct communication with the sea (Moore, 1999). SGD is any combination of terrestrially-derived freshwater mixed with recirculated seawater, which is discharged to the sea through subterranean estuaries (Moore, 1999). Temperatures of SGD are usually either colder or warmer than waters receiving the discharge. SGD occurs at a wide variety of scales and is typically less saline than seawater, forming point-sourced plumes and diffuse, non-point-sourced discharges, which commonly float upon seawater.

SGD can impact coastal zone biogeochemistry through transfer of pristine and anthropogenically-enhanced fluxes of biologically available nutrients, trace metals, carbon, and bacteria to oceans (Krest et al., 2000; Moore et al., 2002; Paerl et al., 2002; Burnett et al., 2007). Because SGD is typically nutrient laden, it can sustain new primary productivity (Giblin and Gaines, 1990; Valiela et al., 1990, 1992; Miller and Ullman, 2004; Paytan et al., 2006; Street et al., 2008), promote coastal eutrophication, and nourish harmful algal blooms (Paerl, 1997; Hu et al., 2006; Bowen et al., 2007; Lee and Kim, 2007). Shifts in dominant flora and fauna within coastal waters (Dollar and Atkinson, 1992; Miller and Ullman, 2004) may result, driving nitrogen-limited coastal primary production to phosphorus limitation (Slomp and Van Cappellen, 2004). The growing national recognition that SGD is a critical pathway for nutrient and contaminant entry to oceans (e.g. National Research Council, 2004) has led to the realization that techniques are necessary to pinpoint and up-scale local SGD assessments to a regional basis.

SGD is spatially and temporally variable, and virtually invisible in plain (visible) light. Locating discharges is therefore challenging, even when relying on the multitude of traditional ground-based methods such as geochemical tracers (radon and radium), temperature, salinity, seepage meters, piezometers, electrical resistivity, and hydrological modeling (e.g. Burnett et al., 2006).

SGD can be identified at the top-most surface of a water body by thermal infrared (TIR) remote sensing. Infrared technology can be used at large scales via satellite, with

individual pixel resolutions of ~60 m to 10's of kms (see Wilson and Rocha, 2012 for a review), or via aircraft at finer scales suitable for detailed SGD characterization, with pixel resolutions better than 5 m. End-users can inexpensively acquire satellite data, which provide broad views of SGD. The coarse spatial resolution of satellite data usually cannot resolve localized features, common for SGD. Collecting airborne TIR data involves costs of hardware and aircraft time, but the imagery can pinpoint SGD on the scales at which individual discharges typically occur. Airborne missions can be designed for any coastline configuration and can be up-scaled or down-scaled by simple adjustments of flight altitude.

Thermographic detection of SGD depends on a difference in temperature between discharging groundwater and seawater. Roxburgh (1985), Banks et al. (1996), and Miller and Ullman (2004) used aerial infrared thermography at high latitudes to study seasonally warm SGD. Portnoy et al. (1998), Shaban et al. (2005), Mulligan and Charette (2006), and Danielescu et al. (2009) used aerial infrared surveying to study seasonally cold SGD at high latitudes. Adams and Lepley (1968), Duarte et al. (2006), and Johnson et al. (2008) used aerial TIR at low latitudes to study groundwater that is colder than seawater. Additionally, Akawwi et al. (2008) used aerial infrared thermography to study geothermally-heated discharge. These studies demonstrate the utility and applicability aerial infrared thermography to a wide variety of settings.

We believe that TIR techniques have strong potential to augment coastal zone studies that utilize temperature contrasts, such as SGD research. One barrier to widespread use of infrared thermography has been the lack of a detailed description to easily conduct an infrared survey and adequately process the resulting data. We present a comprehensive description of our methodology for aerial TIR data collection, post-flight data processing, and image interpretation to detect and quantify any thermal anomaly in coastal zones, including SGD. We demonstrate high-resolution differentiation and mapping of point-source and non-point-source SGD flows, and illustrate variances in data collection at different altitudes. We also provide insight for distinguishing SGD from radiance anomalies created by beach sands, mudflats, shoreline vegetation, shallow waters, and other potential sources of false SGD. Finally, we show that high-resolution TIR imagery can be applied to up-scale groundwater flux measurements to the sea.

Materials and Procedures

Flight Track Planning

Our flight tracks were designed to contain land for manual tie-point georeferencing in the event of INS/GPS (inertial navigation system and global positioning system) system failure. Flight tracks varied in length and were designed to best fit the coastline. For coastal areas larger than the physical area viewable by our camera configuration, multiple, adjacent flight tracks were necessary. Adjacent flight tracks were designed with 30% overlap to maximize continuous sea-surface temperature (SST) mapping. This overlap also provided allowances for aircraft deviation from the planned flight track and aircraft movements such as roll and pitch.

Equipment

For the majority of our research, we used a FLIR Systems Inc. (Portland, Oregon) Photon 320 uncooled microbolometer array camera. This camera has a 320 X 240 pixel detector array and operates in the 8.5-13.5 μm region of the electromagnetic spectrum. The camera's range reduces sensitivity to atmospheric water and carbon dioxide. The measured sensitivity of the camera is 20 mK, well below environmental variables. A 25 mm focal length lens was used on the camera, giving an angular sample of 1.5 mrad/pixel and a camera field of view of 27.5 X 22.0°.

A temperature-adjustable blackbody with a flat-panel design accurate to within 0.1°C was used to calibrate the infrared data during our flights. All calibration temperatures were chosen to bracket the temperatures of the water of interest.

A combined INS/GPS monitored aircraft velocity, roll, pitch, heading, and the three-dimensional position of the aircraft during the flight. This system (C-MIGITS™ II manufactured by BEI Systron Donner Inertial Division, Concord, California and operated in standard positioning service (SPS) mode) has rated performances of 78 m three-dimensional position, 45 m circular error probable horizontal position accuracy, and 52 m vertical error probable vertical position accuracy. Horizontal velocity accuracy is 0.5 m/s, vertical velocity accuracy is 1.0 m/s, roll and pitch accuracy is 2.5 mrad, and heading accuracy is 3 mrad.

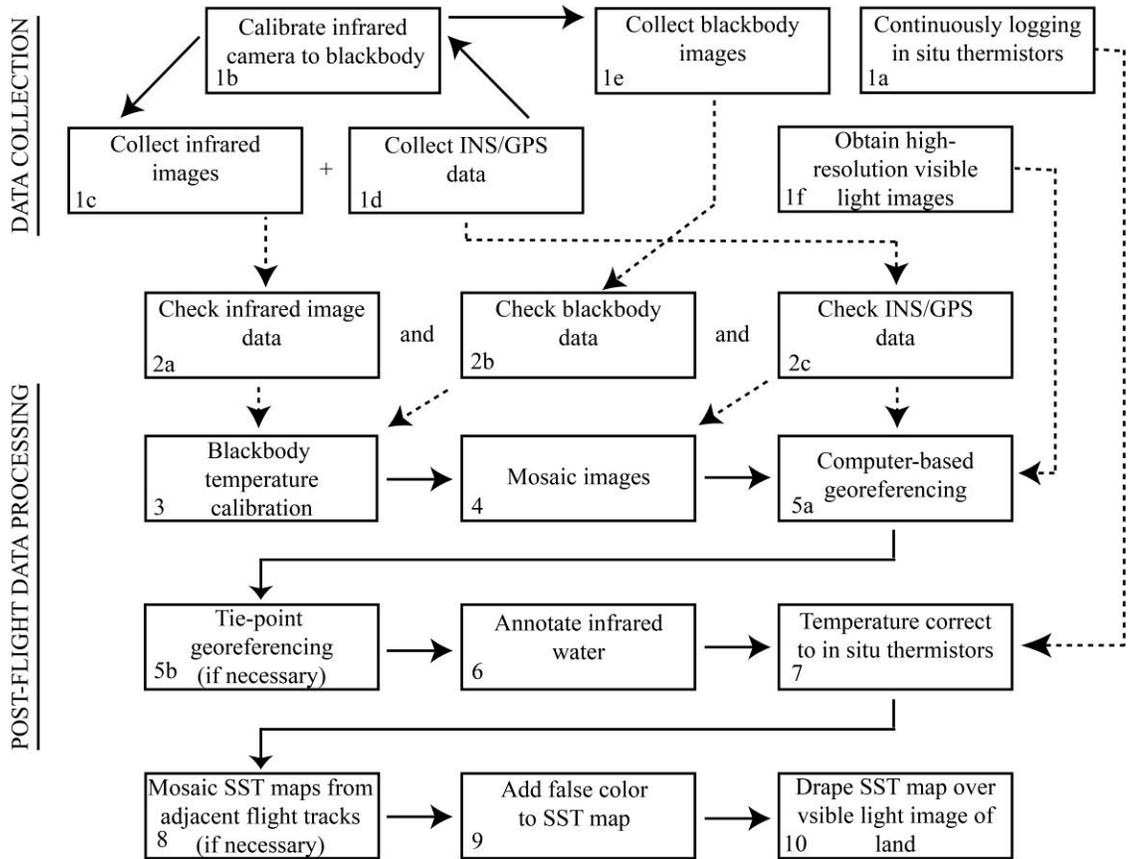

Figure 2.1: Data collection and post-flight data processing flowchart. Boxes represent processes, solid arrows show the progression from one process to another, and dashed arrows indicate the required data for each process. The “if necessary” steps may be bypassed.

The infrared system (camera, blackbody, INS/GPS, and data collection computer) was operated in a twin engine Piper Navajo. We designed and custom built a camera mount that fit into the aircraft’s hull. The camera was affixed to the top of the mount with nadir view. The top and bottom of the mount were separated by vibration isolators that dampened aircraft vibrations and resonant frequencies. Except for vibration isolation, the camera was not otherwise stabilized. The blackbody calibration plate was incorporated into the camera mount directly below the camera. The plate was affixed on roller bars allowing manual movement out of the camera’s field of view during data acquisition and movement into the camera’s field of view for calibration. This integrated arrangement allowed blackbody calibration in-between every flight track during our flights.

Data Collection

Data acquisition (Figure 2.1) included collecting 100 low-temperature calibration images of the blackbody followed by 100 intermediate-temperature calibration images (Figure 2.1, boxes 1b and 1e). Flight track images were then collected (Figure 2.1, box 1c), followed by 100 high-temperature calibration images of the blackbody (Figure 2.1, box 1e). We collected 100 calibration images to reduce random noise in the calibration data to values well below inherent noise in the scene data. All images were collected at a frame rate of 30 Hz. INS/GPS data were simultaneously collected with image data (Figure 2.1, box 1d). This process was repeated for every flight track (Figure 2.1, boxes 1b-1e).

Image Processing

Software

We used ENVI+IDL (Exelis, Boulder, Colorado) to process our data. We could have also easily processed our data using Matlab (MathWorks, Natick, Massachusetts) or ERDAS (Intergraph, Norcross, Georgia), for example. Our processing methodology, described below, is generalized enough to be adapted to any of these software packages.

Data Inspection and Quality Control

We inspected all INS/GPS data for quality and completeness (Figure 2.1, box 2c). We also inspected all coastline images (Figure 2.1, box 2a) and blackbody images (Figure 2.1, box 2b) for quality and completeness.

Temperature Calibration

To calibrate all coastal images, the camera observed the surface of a single, uniform flat-panel blackbody that produces known responses from known inputs. Data were converted from digital counts (DN) to temperature (Figure 2.1, box 3) using low- and-high-temperature blackbody observations to determine pixel dependent gains

$$\text{gain}_{xy} = (T_h - T_l) / (\text{DN}_{xy, Th} - \text{DN}_{xy, Tl}) \quad (2.1)$$

and offsets

$$\text{offset}_{xy} = T_h - \text{gain}_{xy} \text{DN}_{xy, Th} \quad (2.2)$$

to calculate the apparent temperature of the water's surface ($T_{surface}$) on a pixel-by-pixel basis, this also removed non-uniformity in the camera sensor:

$$T_{surface} = gain_{xy}DN_{xy,surface} + offset_{xy} \quad (2.3)$$

where $gain_{xy}$ is gain in units of °C/DN, T_h and T_l are the high- and low-blackbody temperatures, $DN_{xy,Th}$ is the DN value for pixel x,y at the high-temperature blackbody calibration, $DN_{xy,Tl}$ is the DN for pixel x,y at the low-temperature blackbody calibration, $offset_{xy}$ is the offset in units of °C, and $DN_{xy,surface}$ is the DN recorded by the camera for pixel x,y.

Image Mosaicking

We accomplished image mosaicking (Figure 2.1, box 4) by constructing a blank array (workspace), appropriately sized to contain all mosaicked images from a flight track. Next, the center of the first image was placed at a known (x,y) coordinate within the array. The image was then corrected for aircraft roll (x-coordinate plane correction) and pitch (y-coordinate plane correction), returning the image to a perfect nadir view. Each image was next rotated to account for aircraft heading. Finally, a latitude and longitude correction placed all images an appropriate distance from the first image, reflecting aircraft movement across Earth's surface. Since total meters in one degree of latitude and longitude vary by geographic location, we used the geographic location of the central image in each flight track to calculate the average meters per degree of latitude and longitude. Variation in aircraft speed was accommodated with this last correction. This correction was also altitude-dependent; the pixel size as mapped on the ground, for example, decreased as the aircraft operated at lower altitudes.

Since we operated over the ocean, we assumed flat-surface topography and constant aircraft elevation for mosaicking our images. We did not correct our mosaicked images for altitude variation.

Average temperature for every pixel was calculated as each image was placed in the array. During mosaicking, pixels representing the same object on the ground were stacked to occupy the same physical space as previously placed images. Temperatures of all stacked pixels were summed, providing a cumulative temperature for each pixel (T_{sum}). Stacked pixels occupying the same physical space were also summed (N_{sum}). An average temperature (T_{ave}) for every pixel was then calculated by:

$$T_{ave} = T_{sum}/N_{sum} \quad (2.1)$$

Every pixel in the resulting image contained temperature, but lacked spatial reference.

Georeferencing

Computer-based georeferencing (Figure 2.1, box 5a) utilized a latitude array and a longitude array of exactly the same size as the blank array described in the previous section. We determined the exact row in the blank array that held the center of the very first image placed during mosaicking. We then gave the appropriate row in the latitude array the latitude coordinate that corresponded to the center of the first flight track image placed during mosaicking. Insertion of the latitude coordinate into the latitude array necessitated the same pitch, roll, and heading corrections that the mosaicked image underwent. Similarly, the appropriate array column was identified and populated with the longitude coordinate of the first image placed during mosaicking. Next, both arrays were populated with the remaining latitude and longitude coordinates. These coordinates were calculated using the pixel size for each flight altitude and the meters per degree of latitude and longitude determined during the previous step. The outcome produced arrays with geographic coordinates that were merged to the image mosaic, creating an infrared image that contained temperature, latitude, and longitude in every pixel.

We obtained 0.3 m resolution georectified visible-light orthoimages from the United States Geological Survey (USGS; <http://hawaii.wr.usgs.gov/oahu/earthdata.html>). Our computer-based georeferenced images were preliminarily draped over these visible light images. Land in the visible light images enabled validation of computer-based georeferencing. Minor adjustments (two to four pixels in each direction) were usually required to better align infrared images to visible light images (Figure 2.1, box 5b). We accomplished this minor adjustment by collecting ground control points during manual tie-point georeferencing.

Water Annotation (Digitization)

Coastlines in infrared images were manually digitized to mask land and clouds, retaining only infrared water (Figure 2.1, box 6). Clouds were distinguished by viewing their movement across sequential images. We removed clouds from the final images

because image mosaicking averaged the colder cloud temperatures in the scene, resulting in false low temperatures that could be mistaken for cold SGD.

Emitted radiation sensed by the detector for pixels immediately adjacent to the shoreline may be a combination of water and land. We made no attempt to un-mix these pixels, choosing instead to remove mixed pixels during digitization. We acknowledge that some mixed pixels may inadvertently remain in the final images.

In Situ Temperature Correction

We recalibrated our mosaicked, temperature-corrected images to continuously logging in water thermistors ($T_{thermistor}$; HOBO pendant UA-001-08; Onset, Cape Cod, Massachusetts) floating at the water's surface (Figure 2.1, box 7). Thermistors were deployed in each flight track and geographic location of all thermistors was determined by hand-held GPS (Garmin eTrex, Olathe, KS) with 15 m accuracy.

Data collection times for the mosaicked images were used to retrieve SSTs from the appropriate thermistors by matching time stamps. In each mosaicked image, temperatures were averaged ($T_{surface,ave}$) from a roughly 10 X 10 m area, corresponding to the thermistor's location. The difference ($T_{correction}$) between $T_{thermistor}$ and $T_{surface,ave}$ was used to linearly correct the entire image by offsetting $T_{surface}$ to $T_{thermistor}$ by $T_{correction}$.

Flight tracks lacking thermistor data (failed thermistor retrieval, for example), were temperature corrected to adjacent flight tracks with thermistor data. Overlapping areas between the temperature-corrected and non-temperature corrected images were delineated. The average temperature difference between the two areas was used to linearly correct the entire image lacking thermistor data to the image with $T_{correction}$. We used the same convention as the $T_{surface}$ and $T_{thermistor}$ correction above to complete this correction.

Mosaicking Multiple Flight Tracks

We mosaicked adjacent and overlapping flight tracks (Figure 2.1, box 8) by merging that adjacent flight tracks. All pixels in overlapping areas of both images were blended by pixel/distance averaging.

Adding False Color and Draping Infrared Water Over Visible Light Images

Infrared images were linearly stretched and maximized to accentuate temperature variation, while leaving all data intact. Color tables were then applied to mosaicked images (Figure 2.1, box 9), prior to draping the infrared water over visible light images (Figure 2.1, box 10). This process produced the finalized image.

Assessment

The Thermal Infrared Region of the Electromagnetic Spectrum

Thermal infrared cameras are sensitive to light in the 3-5 or 8-14 μm atmospheric windows. Most remote measurements of water utilize the 8-14 μm window where blackbody emission for objects at typical temperatures has peak emitted power (Campbell, 2002). For SGD studies, the signal perceived by the camera is the sum of radiance emitted by the water's surface, partially attenuated by atmospheric radiance, and environmental radiance reflected off the water, whereby:

$$L_{\text{sensor}} = B(T)_{\text{water}} \epsilon_{\text{water}} + L_{\text{downwell}} R_{\text{water}} + L_{\text{atm}(\text{surface-sensor})} \quad (2.5)$$

L_{sensor} is the at-sensor radiance, $B(T)_{\text{water}}$ is blackbody emission of the water at temperature T , ϵ_{water} is water emissivity, L_{downwell} is atmospheric downwelling radiance, including clouds, R_{water} is the bidirectional reflectance function of the water surface at the time of observation, and $L_{\text{atm}(\text{surface-sensor})}$ is atmospheric radiance emitted between the water's surface and the sensor. Under clear sky and relatively smooth surface water conditions, most of the signal reaching a detector positioned with nadir view (vertically downward) is derived from the water's surface. The reflected term is small because of water's low reflectance and very low sky emission under clear conditions; atmospheric radiance is also low, away from water vapor and carbon dioxide emission near 8 and 14 μm , respectively (Campbell, 2002). Subtle

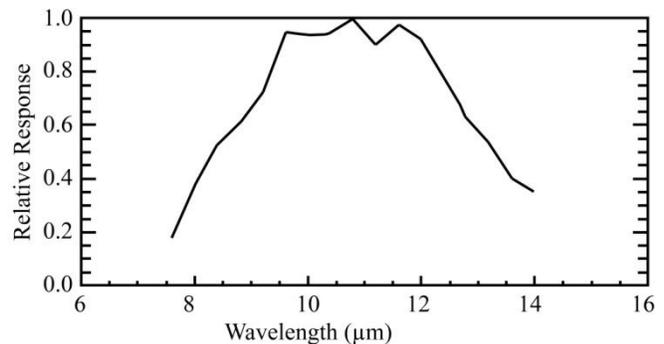

Figure 2.2: Response of the Photon 2.0 infrared camera to a fixed change in temperature. Data were collected with a calibrated spectroradiometer.

temperature differences are detectable even though water vapor and carbon dioxide absorb some of the energy across the window's spectrum (Short, 1982). The sensitivity of a particular sensor to water and carbon dioxide emission and absorbance depends upon the sensor's spectral response across the atmospheric window. Our camera has very low response short of 9 μm and longward of 13 μm , (Figure 2.2).

Table 2.1: Comparison of spatial resolutions, swath widths, and pixel advancements per frame for Oahu's flight missions. Pixel advancement per frame assumes a constant aircraft operating speed of 161 km/h.

Altitude (m)	Spatial resolution (m)	Swath width (m)	Advancement (pixels/frame)
975	1.5	474.6	1.0
1295	2.0	630.3	0.8
2134	3.2	1038.1	0.5

Data Collection

Several factors must be considered when determining the appropriate time to collect infrared data. First, water is almost opaque in the thermal infrared region of the electromagnetic spectrum (8-14 μm). The camera, therefore, cannot see through clouds. Second, rough water surfaces will experience diffusing effects that direct high atmospheric radiance from the horizon toward the sensor. Turbulent water and large waves may also mask SGD by mixing the water column. Third, during the day, sunlight produces temperature anomalies by unevenly heating water or suspended matter in shallow water columns. Furthermore, day-time missions usually require flight track alignment directly toward or directly away from the sun (Myers and Miller, 2005). We have determined that TIR data are best collected when cloud cover is minimal, seas are tranquil, and tide is low, maximizing groundwater flow and signal. For example, we collect data when there is a 0% chance of precipitation, cloud cover is forecasted to be <20%, surf is typically <0.6 m, 0.3 m is better, and tide is down-going to the lowest-low tide of the day. We also avoid mapping water heated from solar radiation (insolation) by collecting data at night. Night operations allow maximum flexibility in flight track

directions and tend to avoid heavy air-traffic situations. Night operations do not require special permissions, permits, or licenses.

Oahu's coastline imagery were obtained on 6 July 2009 between 00:20 and 04:45 a.m. HST (Hawaii Standard Time), 17 July 2009 between 00:55 and 05:35 a.m. HST, and 22 July 2009 between 00:20 and 02:55 a.m.

HST. Most data from Oahu were collected at 2134 m altitude, giving a swath width of 1038.1 m and a pixel size of 3.2 m (Table 2.1). Each consecutive image advanced 0.5 pixels/frame at our targeted aircraft ground speed of

161 km/h (Table 2.1). Data from the island of Maui were collected on 26 May 2011 between 00:00 and 03:15 a.m. HST. Data from the island of Hawaii were collected on 1 May 2007 between 07:53 and 10:30 a.m. HST using a different sensor (Johnson et al. 2008) than described within.

Temperature Calibration

Our gain and offset temperature calibration (equations 2.1-2.3) assumed a linear relationship between DN and temperature, which is strictly incorrect. The camera responds linearly to total power incident on each of its detectors that is proportional to the radiance integrated over the bandpass. However, over the very small temperature range of our calibration, the error caused by our use of gains and offsets was always $<0.25^{\circ}\text{C}$, compared to calculating temperatures using the Planck Equation.

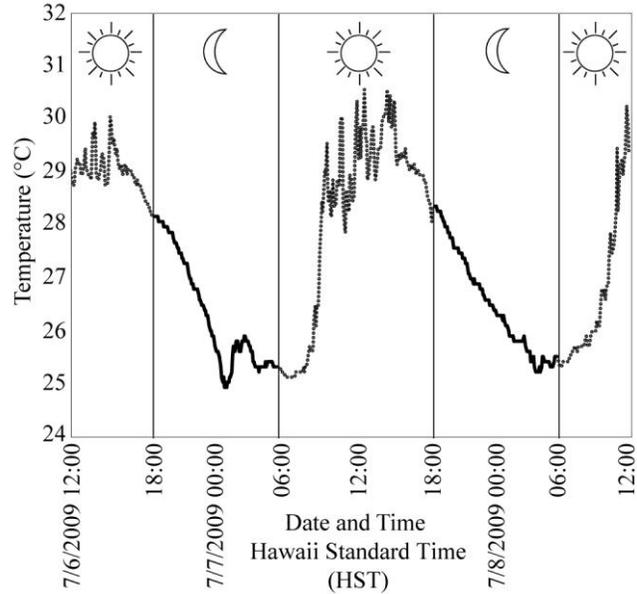

Figure 2.3: Surface water temperatures recorded by a thermistor ($21^{\circ}22'31.3''\text{N}$, $157^{\circ}58'33.7''\text{W}$, WGS84). Solid lines represent nighttime temperatures and dotted lines represent daytime temperatures. Warmest temperatures during daylight hours reflect thermistor heating, not true water temperatures. Nighttime temperatures are accurate SSTs.

Thermistors

Figure 2.3 depicts a typical example of in-water temperatures collected from one of our Oahu, Hawaii flight missions. Water cooled after sunset, stabilized to within 1°C from midnight to sunrise, and rapidly warmed after sunrise. For all Oahu missions, we chose an optimum flight-time window between midnight and 6:00 a.m. HST. Thermal contrast between SGD and ocean water is not at maximum during this time, although temperature differences between groundwater (19 and 21°C; Visher and Mink, 1964) and coastal water (24 to 28°C) were easily differentiated with our measurement precision (1°C). Figure 2.3 also shows that correcting infrared images to daytime temperatures recorded by our thermistors floating at the water's surface would result in inaccurate SST maps due to greater thermistor heating than water heating. In practice, determining in situ temperatures prior to data collection is highly recommended for establishing optimal flight times, especially since optimal times will vary seasonally and with location.

Sea Surface Effect

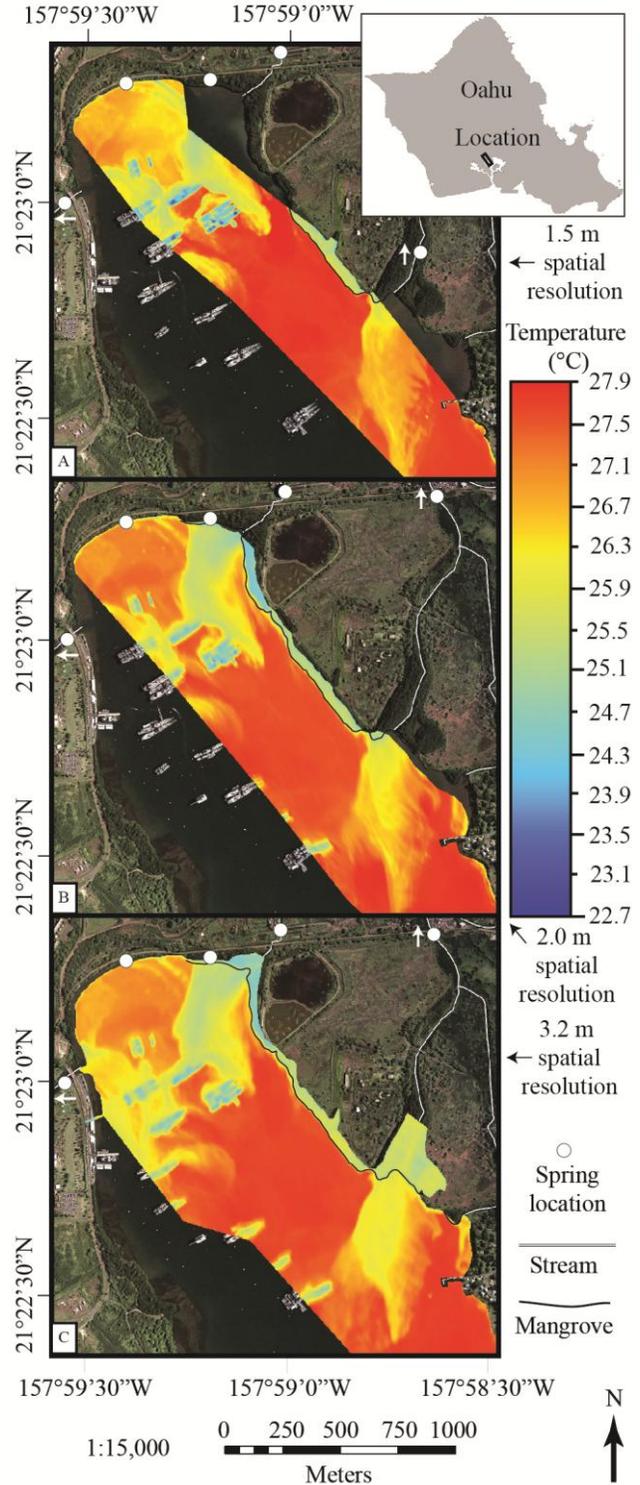

Radiance emitted from the ocean's surface is absorbed by water vapor, carbon dioxide, and aerosols in the atmosphere. As a result, radiance reaching the airborne sensor is reduced, leading to colder calculated surface temperatures ($T_{surface}$) than actual skin-water temperatures ($T_{thermistor}$). Calibrating $T_{surface}$ to $T_{thermistor}$ may result in erroneous water temperatures since liquid water is opaque in the 8-14 μm region of the electromagnetic spectrum. Due to the camera's perceived opaque nature of water, emission sensed by the detector is derived from a thin skin at the water's surface. This is called the "sea surface effect" (Schluessel et al., 1990; Banks et al., 1996; Fisher and Mustard, 2004). Bulk water temperatures are, therefore, not strictly determined by TIR remote sensing (Brown et al., 2005), since temperature micro-gradients between surface and bulk water exist (Fisher and Mustard, 2004). Skin temperatures are colder than bulk water due to evaporative cooling (Handcock et al., 2006); however, temperature differences between skin and bulk water are usually between 0.3 and 0.5°C (Schluessel et al., 1990; Emery et al., 1994; Donlon et al., 1998; Emery et al., 2001). Evaporative cooling did not obscure the underlying signals as SGD anomalies were apparent in our data. Evaporative cooling appeared to be an offset.

Figure 2.4: Altitude comparison study of Middle Loch, Pearl Harbor, Oahu on 22 July 2009 (A) 975 m altitude; 1.5 m spatial resolution; 02:49 to 02:52 a.m. HST, (B) 1295 m altitude; 2.0 m spatial resolution; 02:43 to 02:45 a.m. HST, and (C) 2134 m altitude; 3.2 m spatial resolution; 02:34 to 02:36 a.m. HST. All panels have the same temperature scale and map scale. The coldest blue rectangle-shaped objects were moored naval ships. Springs adjacent to white arrows indicate USGS monitoring locations outside of the area shown in the figure. In situ temperature, salinity, and ^{222}Rn surface water surveys (Chapter 3) confirmed a relationship between cold water and submarine groundwater discharge. →

For SGD research, relative temperature differences between pixels are more important than absolute temperatures assigned to each pixel. When accurate temperatures are required, more accurate temperature loggers should be deployed and quantification of the "sea-surface" effect must be completed.

Altitude Comparison Study

Spatial resolution obtained from any fixed focal-length camera system is dependent on flight altitude. We tested three flight altitudes (Table 2.1) by collecting sequential TIR images over the Middle Loch estuary of Pearl Harbor, Oahu

(Figures 2.4A-C), an area with known SGD (Visser and Mink, 1964; Oki, 1998). All panels in Figure 2.4 were collected at the same tidal stage. Honolulu tide (NOAA gauge 1612340) was +0.17 m relative to mean low-low water. All panels are displayed with the same temperature and map scales to allow unbiased comparison. Figures 2.4A-C illustrate that the flight operation at the moderately high altitude (2134 m) was sufficient to discern SGD. Higher altitude surveying generated larger swath widths, providing greatest aerial coverage (Figure 2.4C). Spatial resolution at the lowest altitude (Figure 2.4A) was over twice that of the highest altitude (Figure 2.4C), allowing discernment of ≥ 1.5 m diameter features in Figure 2.4A. Sharpest images were therefore generated at the lowest altitude. The exposed coastline in the east, north-east section of each panel is delineated by a black line. This line separates water from mangroves, which have comparable temperatures to SGD. Similar temperature characteristics are evident in all images indicating that the lowest resolution imagery, and therefore most cost-effective survey, was adequate for mapping the scale of SGD throughout this estuary.

Thermal Signatures from Beach Sands, Shoreline Vegetation, Mudflats, and Coral Reefs

Relatively rapid nighttime cooling caused some coastal features to have similar temperatures as SGD. Some interfering features included beach sands, shoreline vegetation, mudflats, and shallow seawater that ponded over coral reefs. In addition, evaporative cooling gave wet beach sands colder temperatures than dry beach sands, which therefore resembled SGD. Shoreline vegetation such as mangroves had similar temperatures as SGD and masked the SGD signal until it reached open water (Figures 2.4A-C). In many situations, we found that simply comparing visible light images and infrared images provided valuable insight regarding radiance interferences (i.e. the mangroves in Figures 2.4A-C). In situ field work may be required to confirm potential SGD occurrences on SST maps that are not obvious by comparing visible light and infrared images.

Mapping Point-Source and Diffuse SGD

Understanding the mechanisms of discharge and the degree to which discharging water interacts with the subterranean estuary is an important objective of most SGD studies. Furthermore, various discharge mechanisms require different in situ sampling

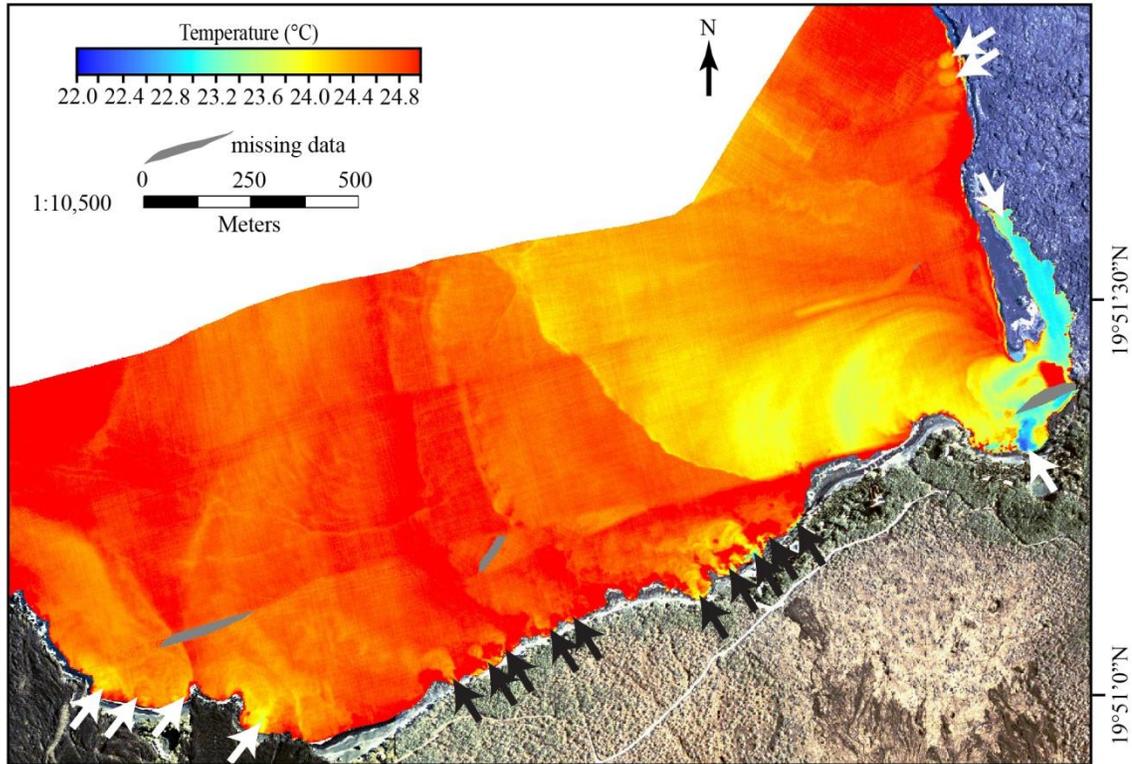

Figure 2.5: Kiholo Bay, Hawaii exhibits at least eighteen point-sourced SGD locations at a variety of scales. All point-sourced plumes are delineated by arrows. This SST map was collected on 1 May 2007 and has 1.3 m spatial resolution (after Johnson, 2008).

strategies. Differentiation of discharge mechanisms ranging from (1) discrete point-source discharges, (2) diffuse, non-point-source seepage, and (3) some combination of both is important for SGD research. Differentiation can be readily accomplished via aerial TIR mapping. To stream-line SGD classification, we define point-source and diffuse flow. Point-sourced discharge is water that emanates outward as a single, spatially well-defined plume or jet that possesses distinguishable temperatures relative to the waters which surround it, and which is resolvable within the spatial resolution of our TIR configuration (≤ 3.2 m in this chapter). We define diffuse SGD as non-point-sourced flow that occurs as a broad-scale distribution with no discernible single input source. Diffuse flow results in a fairly large area of relatively uniform temperature-water that is anomalously cold or warm relative to the surrounding water. Figure 2.5 illustrates at least eighteen point-sourced SGD plumes emanating from young basalts at Kiholo Bay, Hawaii. Of 50 large SGD plumes mapped by TIR along the western half of the island of Hawaii, the spatially largest and quantitatively most voluminous discharge emanates

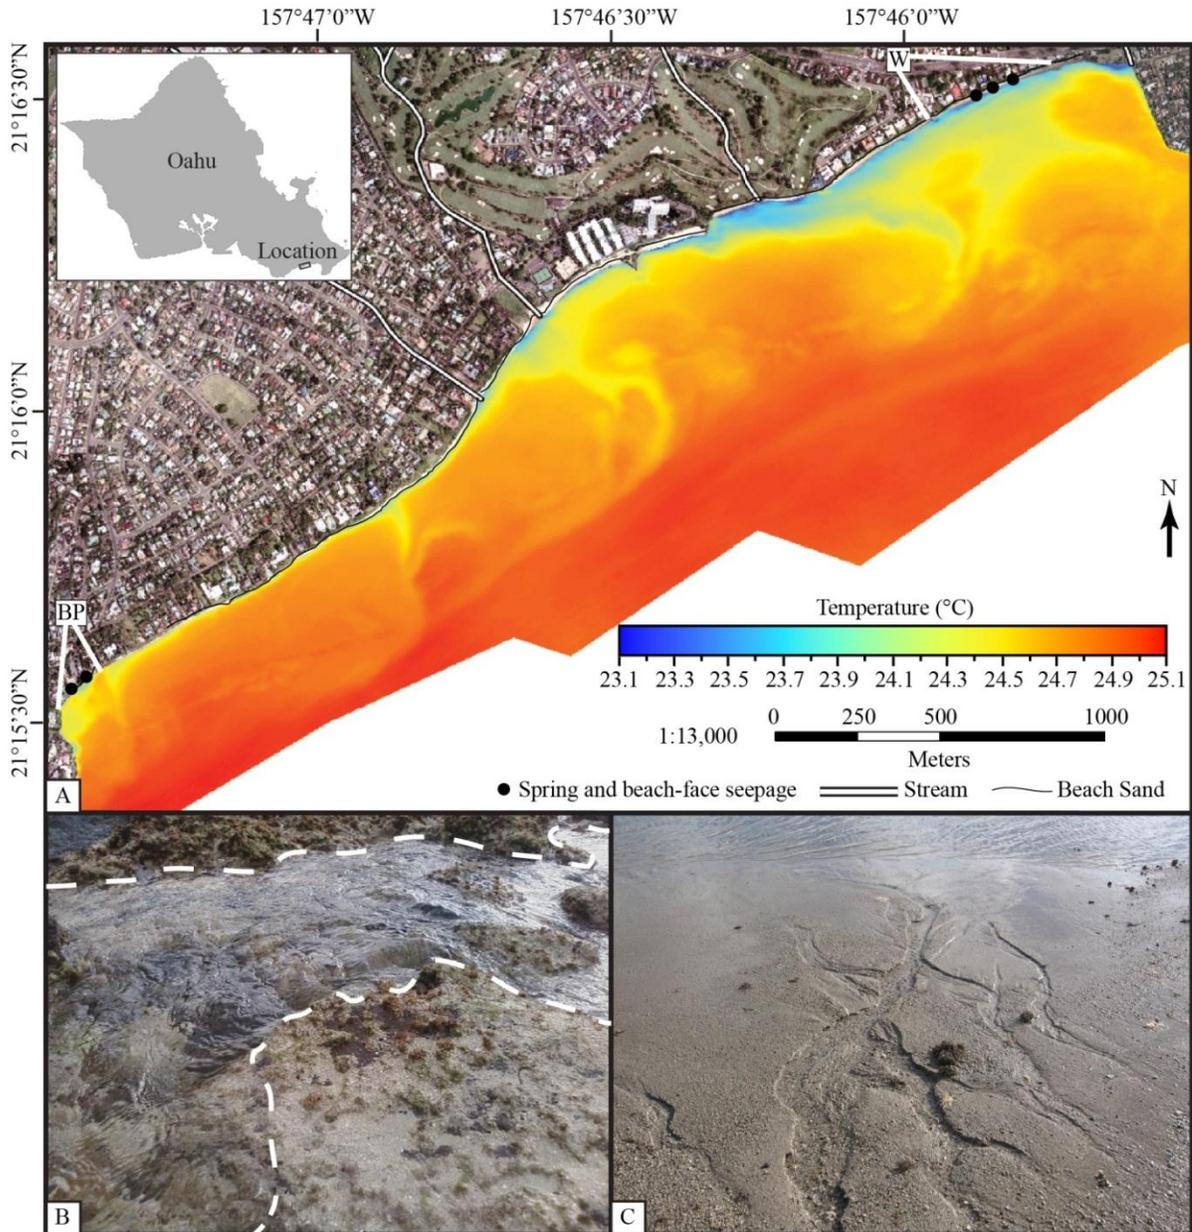

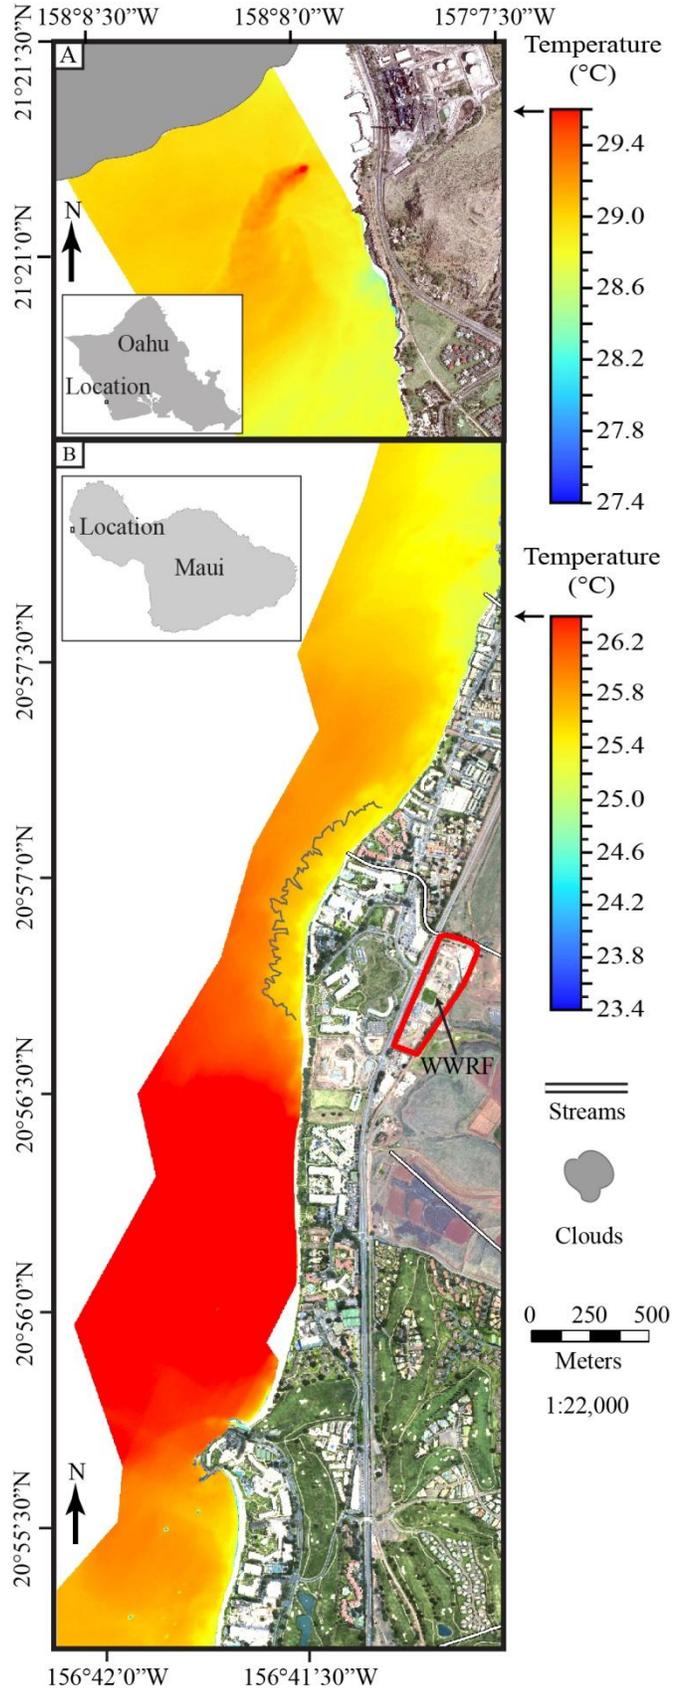

Figure 2.6: SGD in Aina Haina, Oahu (A) TIR image showing predominantly diffuse flow. This SST map was collected on 22 July 2009 between 2:01 and 2:06 a.m. HST when Honolulu tide was +0.16 m. This image has 3.2 m spatial resolution. Stream beds were dry during data collection, so cold water (blue hues) along the shore was exclusively SGD. Black Point (BP) exhibited groundwater springs resulting from artesian pressure (B). The white dashed line marks the boundary of the spring, which disturbed the otherwise flat water surface. Diffuse SGD in this area was also augmented by groundwater beach-face seepage such as rivulets (C) at Wailupe Beach (W). These rivulets are especially evident at low tide. Horizontal dimensions of (B) and (C) are ~1 m.

Figure 2.7: Hot water plumes from Kahe Power Plant outfall near Nanakuli, Oahu (A) and heated coastal waters near Lahaina, Maui (B). The 3.2 m resolution SST map in (A) was collected on 17 July 2009 between 4:51 and 4:59 a.m. HST when Honolulu tide was -0.04 m. The 2.3 m resolution SST map in (B) was collected on 26 May 2011 between 12:45 and 12:49 a.m. HST when Lahaina tide was +0.25 m. The SST map in (B) is draped over a 0.5 m resolution, orthorectified visible light image from DigitalGlobe Inc. (Longmont, Colorado). Both panels are at the same map scale.

from the single inlet on the east side of this bay (blue hues; Johnson, 2008; Peterson et al., 2009). Diffuse SGD was also readily identified in our high resolution imagery. An excellent example, illustrated in Figure 2.6A, concerns Oahu's south shore. In this area, groundwater seepage was dispersed through confining layers that contained fine-grained mud, marl, and basalt weathering products (Nichols et al., 1996). These rock properties created conditions conducive for diffuse discharge

where the few known point-source inputs (Figures 2.6B-C) occurred below the 3.2 m resolution of Figure 2.6A. McGowan (2004), Bukunt (2006), Swarzenski et al. (2009), and Holleman (2011) have all demonstrated prominent SGD in this area.

Hot Water Sources

Examples of TIR mapping of hot water plumes are illustrated in Figures 2.7A-B. Kahe Power Plant, on Oahu, discharges warm water via an underwater outfall pipe ~250 m offshore in 8 m of water (Figure 2.7A). Outfall water is approximately 5 to 6°C warmer than ocean water (Lager, unpublished data 2011 available at http://cramp.wcc.hawaii.edu/LT_Monitoring_files/lt_study_sites_Oahu_Kahe_Point.htm). The outfall introduces freshwater that buoyantly floats to the ocean's surface, cooling as it flows upward (Figure 2.7A). In comparison, near Lahaina, Maui, warm waters are vented to the ocean's surface via benthic point-source seeps and diffuse flows (Figure 2.7B). SCUBA divers noted anomalously warm water disseminating from several small (<1 km area), localized seeps, but the SST map revealed the true lateral extent of the thermal impact to the coastal zone. Seasonally warm discharge at high latitudes, for example, will therefore be detectable with our camera configuration and post-flight processing methodology.

Estuary and Coastal Oceanic Mixing and Currents

Airborne TIR imagery also conveyed information about coastal mixing. Figure 2.6A shows >4 km of coastline with abundant diffuse discharge (blue hues) to the ocean. The discharge was pulled to the northeast by a nearshore current and then to the southwest by an offshore current. The hot water plume from Kahe Power Plant in Figure 2.7A provides another example, where surface waters were mixed toward the south. Evaluation of mixing between surface water and groundwater was also possible using SST maps. In Middle Loch (Figures 2.4A-C), groundwater-fed streams thermally impacted the estuary's surface waters to a greater spatial extent than cold spring sources at the back of the loch. Moored naval ships also bifurcated the flows.

TIR-Derived Plume Areas and In Situ Groundwater Fluxes

A major achievement for aerial TIR remote sensing is the quantitative application of SST data to study terrestrially-derived groundwater discharge in the coastal zone. Our research demonstrated a direct, positive correlation between SGD plume areas mapped by aerial infrared thermography and volumetric discharge. This achievement greatly advanced our ability to study and up-scale SGD fluxes.

Two-dimensional surface areas of SGD plumes were determined from TIR imagery. We defined the outer edge of each plume by averaging the maximum change in temperature, or inflection point (Johnson, 2008) from several transects drawn either from the source of input, or laterally across the plume (Figure 2.8A). Averaged maximum-temperature inflection-points (Figure 2.8B) were then contoured to define the outer boundary of each plume (Figure 2.8C).

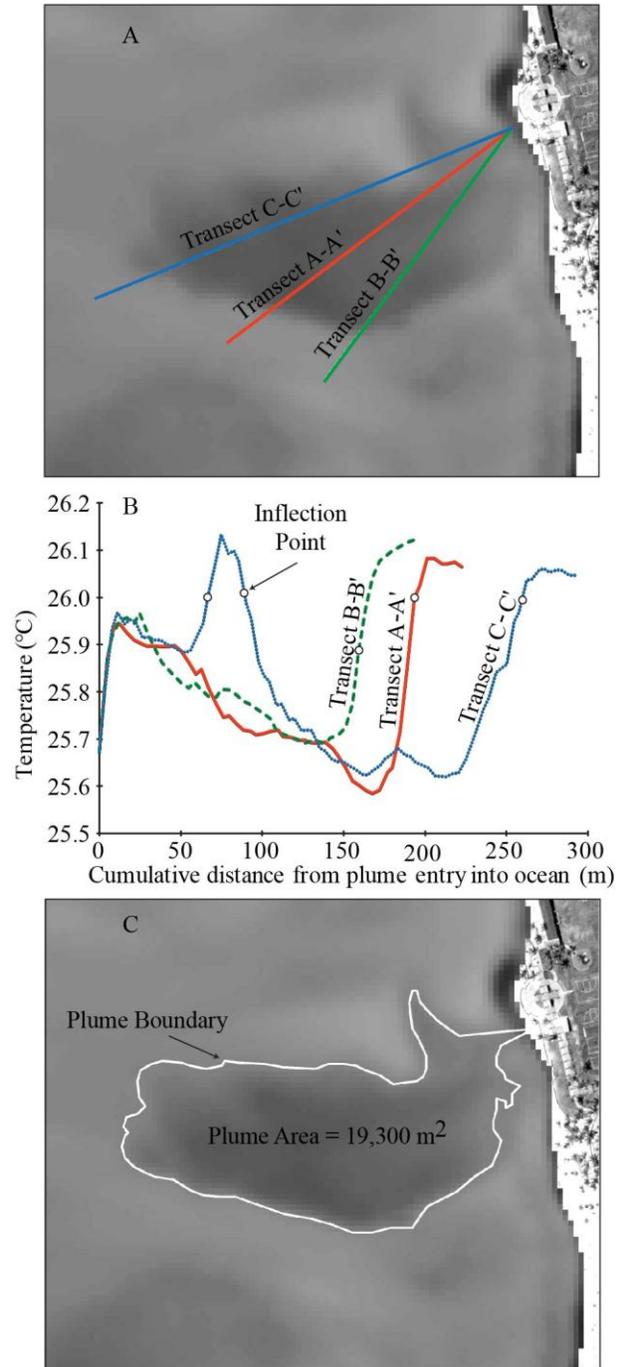

Figure 2.8: Surface areas of groundwater plumes (A), represented by the darkest hues, are calculated by determining the steepest inflection points of a family of linear temperature curves (B) to calculate an average temperature for the plume boundary, which is contoured (C) to enclose the overall plume and used to calculate the surface area.

Figure 2.9 shows the correlation between surface areas of plumes and groundwater fluxes determined via ^{222}Rn mass balance for Pearl Harbor, Hawaii (see Chapter 3). The strong correlation in Figure 2.9 likely results from the buoyant discharge. Discharge to the Pearl Harbor field area was likely influenced by similar geologic features and coastal mixing characteristics. These factors will likely change the slope of the line to be specific to a particular field area. For example, Johnson (2008)

demonstrated a similar relationship with a slope of 0.1 for the west side of the island of Hawaii using ^{222}Rn mass balance to calculate groundwater fluxes. Danielescu et al. (2009) also found a similar linear relationship with a slope of 0.00006 between TIR plume areas and spring discharge rates calculated using portable flumes for two watersheds on Prince Edward Island, Canada. We hypothesize that once a region has been mapped via TIR, and some certainty of groundwater fluxes has been established, regional up-scaling of coastal groundwater discharge is possible.

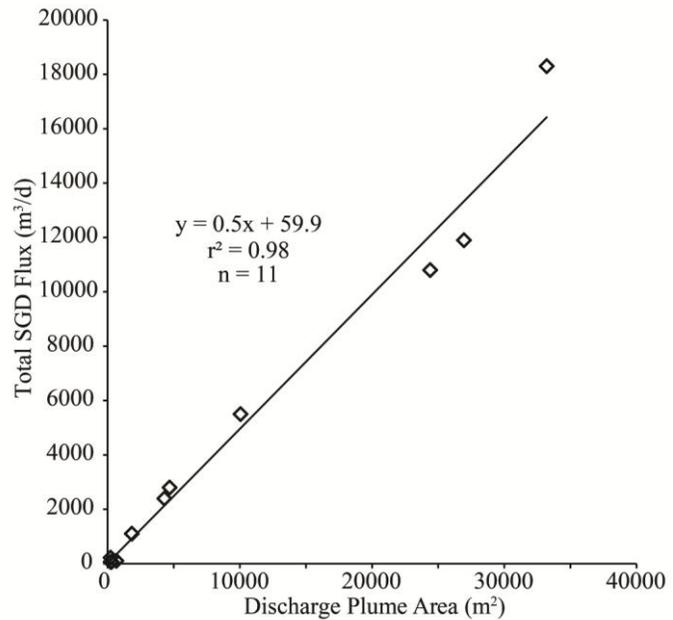

Figure 2.9: Submarine groundwater discharge flux (fresh plus saline water) measured from ^{222}Rn time-series platforms in Pearl Harbor, Hawaii (see Chapter 3) plotted relative to plume areas determined from SST maps.

Discussion

Our data collection and post-flight data processing techniques provide some of the crispest, clearest, and most precisely georeferenced images compared to previously published results. The imagery readily shows the precise occurrences of the surface expression of groundwater discharge with the detail necessary differentiate between point-source and diffuse flow. The nadir camera configuration eliminates additional processing required for oblique-view infrared missions (Miller and Ullman, 2004; Duarte

et al., 2006). Furthermore, the rapid computer-based georeferencing (<10 minutes to georeference an entire flight track) eliminates the need for hours of manual to-point georeferencing. Manual tie-point georeferencing also has the disadvantage of distorting and warping images if too few ground-control-points are selected. The nadir camera configuration and computer-based georeferencing greatly reduces the time required for post-flight data processing. Our post-flight data processing routine also removes non-uniformity of the detector, which makes image interpretation simple. Additionally, the accurately georeferenced images allow us to determine exact locations of thermal anomalies and use those geographic coordinates to precisely locate the discharge during field operations.

Since aerial TIR imagery can be collected at a variety of altitudes, the spatial resolution can be varied to investigate coastal zone processes at a variety of scales. This is a distinct advantage over satellite data. SGD's typically buoyant nature and anomalous temperatures relative to seawater allow for its rapid and accurate detection by aerial TIR remote sensing. At minimum groundspeeds of 161 km/h, airborne TIR remote sensing affords rapid data acquisition over large stretches of coastline in a short time. We typically image 40 km of coastline per hour at a cost of less than \$40.00/km, excluding camera and associated equipment expenses (~\$50,000).

The biggest advantage of aerial infrared surveying compared to the more traditional methods used to study SGD is its ability to collect large quantities of data over large stretches of shoreline in a short amount of time. The high-resolution data also provides information about the precise groundwater discharge location, the discharge's surface expression, and whether the discharge is point-source flow or diffuse flow. A disadvantage of the technique compared to more traditional techniques is its ability to only detect the very surface of the water column. This method cannot detect vertical variability or stratification in the water column. The method also cannot detect discharge that does not reach the water's surface or discharge that is similar in temperature to the surrounding water.

TIR data are customarily employed for qualitative assessment of coastal zone processes. We have demonstrated that aerial TIR data is also a quantitative tool useful for calculating surface plume areas. The ability to calculate plume areas allows us to

prioritize field measurements. We have also established that TIR data can be used for up-scaling SGD to regional basis, once some knowledge of flux rates is attained for a field area. This is a powerful application of TIR data that can be applied to research sites world-wide.

In conclusion, we recommend that thermal infrared remote sensing be added to the many techniques used to study SGD. The imagery allows SGD researchers to (1) obtain a regional-scale view of SGD with knowledge of precise discharge locations, (2) determine whether the discharge is point-source or diffuse, (3) streamline field operations, (4) calculate plume areas, and (5) qualitatively estimate groundwater discharge fluxes for large field areas with only a few in situ flux measurements.

Comments and Recommendations

Our technique is also applicable to any lake or coastal zone process that involves temperature contrasts between water bodies. Although we use this technique to study SGD, impacts of stream/river mixing in estuaries and coastal zones, power plant outfalls, and nearshore current studies, for example, are all attainable with the techniques and methods presented herein.

Our work demonstrates that a variety of coastal and estuarine field-based studies can benefit from high-resolution aerial SST maps generated by aerial infrared thermography. Selection of groundwater sampling sites, estimation of environmental effects of contaminant mitigation, evaluation of nearshore ecosystems impacts, detection of nearshore currents, determination of seaward mixing characteristics of discharging water, and improvement of groundwater contour maps can all be aided by SST maps. In situ field measurements of SGD tracers such as salinity, radon, and radium, as well as sub-seafloor resistivity investigations can be used in combination with TIR data to investigate field sites at a variety of scales using independent techniques.

Our methodology can be easily adapted for helicopter flight missions and ground-based studies. For ground-based studies, geographic location corrections will not be necessary; however, ground-based studies usually require oblique camera viewing angles. Data processing will have to be amended to include corrections for these oblique viewing angles.

CHAPTER 3. GROUNDWATER FLUXES TO PEARL HARBOR, HAWAII DETERMINED BY RADON AND THERMAL INFRARED SURVEYS

Introduction

Submarine groundwater discharge (SGD) is a globally important process that introduces terrestrially-derived constituents to coastal ecosystems. Although SGD flux to coastal areas may be lower than surface water inputs, concentrations of dissolved constituents in SGD are often much higher than surface waters (Zektser et al., 2006). Discharge can, therefore, impact coastal ecosystems leading to eutrophication, harmful algal blooms, and shifts in the dominant flora and fauna of coastal waters (Dollar and Atkinson, 1992; Paerl, 1997; Miller and Ullman, 2004). SGD occurs throughout the Hawaiian Islands (Derse et al., 2007, Peterson et al., 2007, Johnson et al., 2008, Street et al., 2008, Peterson et al., 2009, Holleman, 2011), but very little is known about the distribution of discharge into and within Pearl Harbor. Pearl Harbor is the largest estuary in the Islands and has the largest freshwater spring complex in the Islands (Englund et al., 2000) with subaerial (shoreline) springs (Nellist, 1953; Visher and Mink, 1964; Nichols et al., 1996), submarine springs (Lau, 1962; Visher and Mink, 1964; Nichols et al., 1996), and diffuse, non-point source groundwater inputs (Hunt, 1996; Nichols et al., 1996; Shade and Nichols, 1996).

Locating groundwater inputs and establishing fluxes for those inputs is desirable for groundwater managers, ecosystems scientists, and environmental impact assessors, particularly if the discharging water contains contaminants or other undesirable constituents. Furthermore, groundwater production from the underlying Pearl Harbor aquifer diminishes spring flow to the harbor, with flow rates less than half of estimated predevelopment rates (Nichols et al., 1996). Direct assessment of groundwater fluxes may also help document changes in discharge and the impact water withdrawals have on the aquifer and the estuary.

Thermal infrared (TIR) surveying is applicable wherever temperature differences exist between discharging groundwater and receiving estuary or coastal water (e.g. Johnson et al., 2008; Wilson and Rocha, 2012). We utilized aerial TIR remote sensing to detect cold groundwater discharge in surface waters of Pearl Harbor. The thermal infrared technique only detects SGD from the vary surface of the water. Radon-222

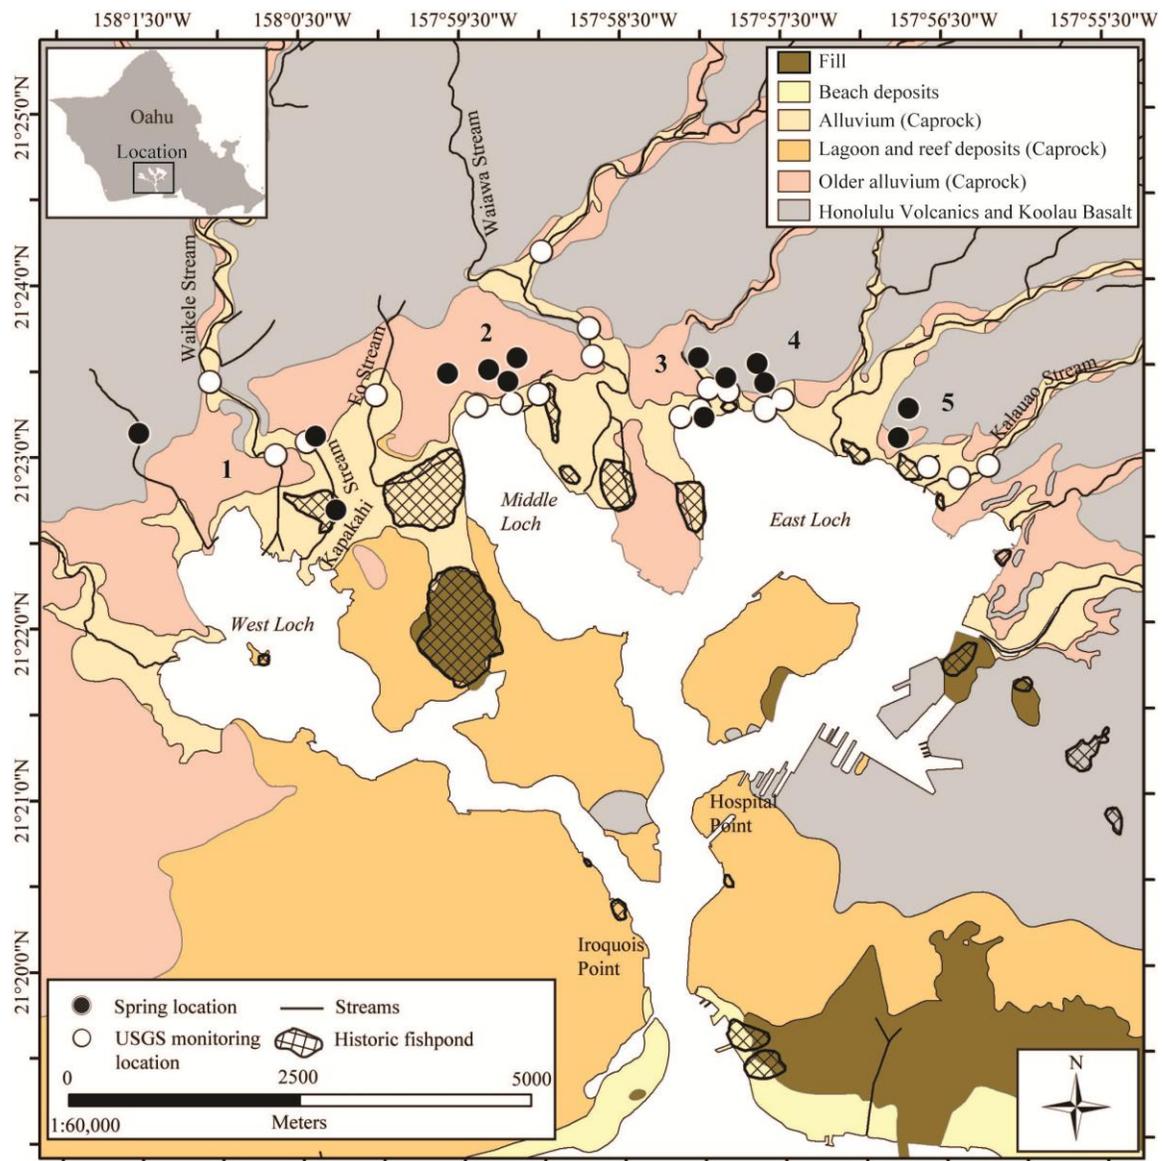

Figure 3.1: West Loch, Middle Loch, and East Loch of Pearl Harbor with respect to the island of Oahu, Hawaii (top left inset map). Five spring systems are identified by numbers: 1) Waikele Springs, 2) Waiawa Springs, 3) Waimano Springs, 4) Waiiau Springs, and 5) Kalauao Springs. Each spring system contains numerous subaerial springs that reside in the vicinity of the number identifier. Spring monitoring stations (United States Geological Survey) are indicated by white dots while other spring locations from Stearns and Vaksvik (1935) are identified by black dots. Streams specifically referred to in the text are labeled, while all other stream names are omitted for figure clarity. Historic fishpond locations are modified from Donn (1902) and Grovhoug (1992). The geologic map is after Sherrod et al. (2007).

(^{222}Rn) is a naturally-occurring radioactive proxy of SGD. It is radioactive-conservative and is enriched in groundwater aquifers (due to natural occurrence of ^{238}U in basalt, a parent isotope of ^{222}Rn) compared to ocean water. This enrichment of ^{222}Rn in groundwater results in a large concentration gradient between the discharging groundwater and the receiving water, making identification of groundwater discharge based on elevated ^{222}Rn activities possible. We used ^{222}Rn to confirm groundwater discharge locations identified in the infrared imagery and to estimate groundwater fluxes to Pearl Harbor. As we discuss below, the ^{222}Rn tracer identified all SGD inputs to the harbor, but only partially identified subaerial spring inputs to the harbor due to ^{222}Rn degassing.

This study additionally explored the relationship between current groundwater discharge locations and historically known fishponds locations. These fishponds are relevant to understanding the area's hydrogeology since they were strategically built around fresh or brackish water sources, including streams and springs.

Field Area

Pearl Harbor (Figure 3.1) is underlain by numerous basalt flows and represents a drowned river system that has been successively flooded and drained as a result of past sea-level changes (Stearns, 1985). Deposition of marine sedimentary rocks (caprock) over much of Pearl Harbor's coastal plain and valley mouth areas (Figure 3.1) ensued during lower sea-level stands (Stearns and Vaksvik, 1935). Increased weathering and erosion rates during lower sea-level promoted production and deposition of fine-grained mud and marl in the caprock (Hufen et al., 1980), giving it low permeability compared to the island's basaltic aquifers. Caprock is thus hydrologically important because it behaves as a confining unit.

The northern boundary of Pearl Harbor is divided into five separate spring systems (Figure 3.1). Each spring system contains several subaerial springs that result from groundwater convergence along a narrow zone between the inland edge of the caprock and 6 m above sea-level (Stearns and Vaksvik, 1935; Visher and Mink, 1964; Hunt, 1996; Nichols et al., 1996). These artesian springs flow because of pressure generated by the confining caprock overlying the basaltic aquifer. The springs represent overflow of pressurized water from the upper part of the groundwater transition zone

(Nellist, 1953; Visher and Mink, 1964; Nichols et al., 1996). Less voluminous subaerial and submarine springs flow from more seaward areas of the caprock that contain only terrestrial sediments and where weathered basalt, marine sediments, and pyroclastic materials are absent (Lau, 1962; Visher and Mink, 1964; Nichols et al., 1996). Groundwater discharge is also believed to occur as diffuse leakage through the caprock and in areas where the caprock is absent or scant (Hunt, 1996; Nichols et al., 1996; Shade and Nichols, 1996).

Nichols et al. (1996) speculated that Pearl Harbor's springs account for approximately 70% of the natural groundwater discharge from the area, with the remainder occurring as diffuse leakage through the caprock. Furthermore, spring flow varies with aquifer head and is greatest during winter when groundwater withdrawals are least and decreases during summer when groundwater is pumped from the aquifer in greater quantity (Hunt, 1996; Nichols et al., 1996; Shade and Nichols, 1996; Visher and Mink, 1964).

Methods

Aerial Thermal Infrared Remote Sensing

We employed high-resolution (2.0 to 3.2 m) aerial infrared thermography to determine temperatures of the top sub-millimeter of the water's surface. All TIR data were calibrated to in situ thermistors (HOBO pendant UA-001-08; Onset, Cape Cod, Massachusetts) that were deployed within flight tracks prior to TIR data collection. These thermistors continuously recorded sea-surface temperatures (SSTs) at five-minute intervals and were retrieved shortly after TIR data collection was completed.

Data were obtained during low-tide conditions at night, while the prevailing sky conditions were clear to mostly-clear. We collected data on 12 June 2009 at 06:27 a.m. Hawaii Standard Time (HST), on 17 July 2009 at 03:50 a.m. HST, and on 22 July 2009 at 02:17 a.m. HST following the methods and camera configuration discussed in Chapter 2. Briefly, a FLIR Systems Inc. (Portland, Oregon) Photon 320 uncooled microbolometer array camera, temperature-adjustable blackbody with a flat-panel design, and combined inertial navigational system and global positioning system (C-MIGITS II; BEI Systron Donner Inertial Division, Concord, California) were affixed to a custom-built camera

mount and installed in the belly of a twin engine Piper Navajo airplane. All TIR images were calibrated to the blackbody before and after each flight track while in flight.

Post-flight data processing was completed following the methods described in Chapter 2. Briefly, data were inspected for quality control, temperature corrected to blackbody calibration data, mosaicked, georeferenced, annotated (digitized) to retain only the water signal, corrected to in situ thermistor measurements of temperature, colorized with false color, and finally, draped over 0.3 m georectified, visible-light orthoimages available at <http://hawaii.wr.usgs.gov/oahu/earthdata.html>.

We determined the temperature of each plume boundary visible in the final infrared images by averaging maximum temperature inflection-points (≥ 6) from multiple transects (≥ 3) across each plume. We then contoured the average temperature of the plume boundary and determined the area within the contour. These calculations are described in greater detail by Johnson (2008) and in Chapter 2.

Discrete samples from Water Supply Wells and Coastal Springs

^{222}Rn activities from ten City and County of Honolulu Board of Water Supply wells and five subaerial springs located in proximity to the shoreline were determined by grab samples collected in either 40 or 250 mL screw-top glass bottles (DurrIDGE Company Inc., Billerica, MA). Samples from the water supply wells were collected using preexisting pumps in the wells, whereas spring samples were collected by hand or by peristaltic geopump (geotech, Denver, CO). Screw-top bottles were filled from the bottom up, allowed to overflow for at least three bottle volumes of water, and sealed, leaving no head-space. All grab samples were analyzed using a RAD-H₂O (DurrIDGE Company Inc., Billerica, MA) and decay-corrected to their time of collection. Temperature and salinity of all water supply wells and coastal springs were also determined at the time of sample collection by either a YSI Model 63 or YSI 6920 V2 (YSI Inc., Yellow Springs, OH).

Stationary Time-Series Deployments, Surface-Water Surveys, and Water-Column Surveys

Three ^{222}Rn measurement strategies were utilized for this study: 1) stationary ^{222}Rn time-series deployments, 2) ^{222}Rn surveys of surface waters, and 3) ^{222}Rn surveys of the water column. For all ^{222}Rn -monitoring strategies, a commercially available ^{222}Rn

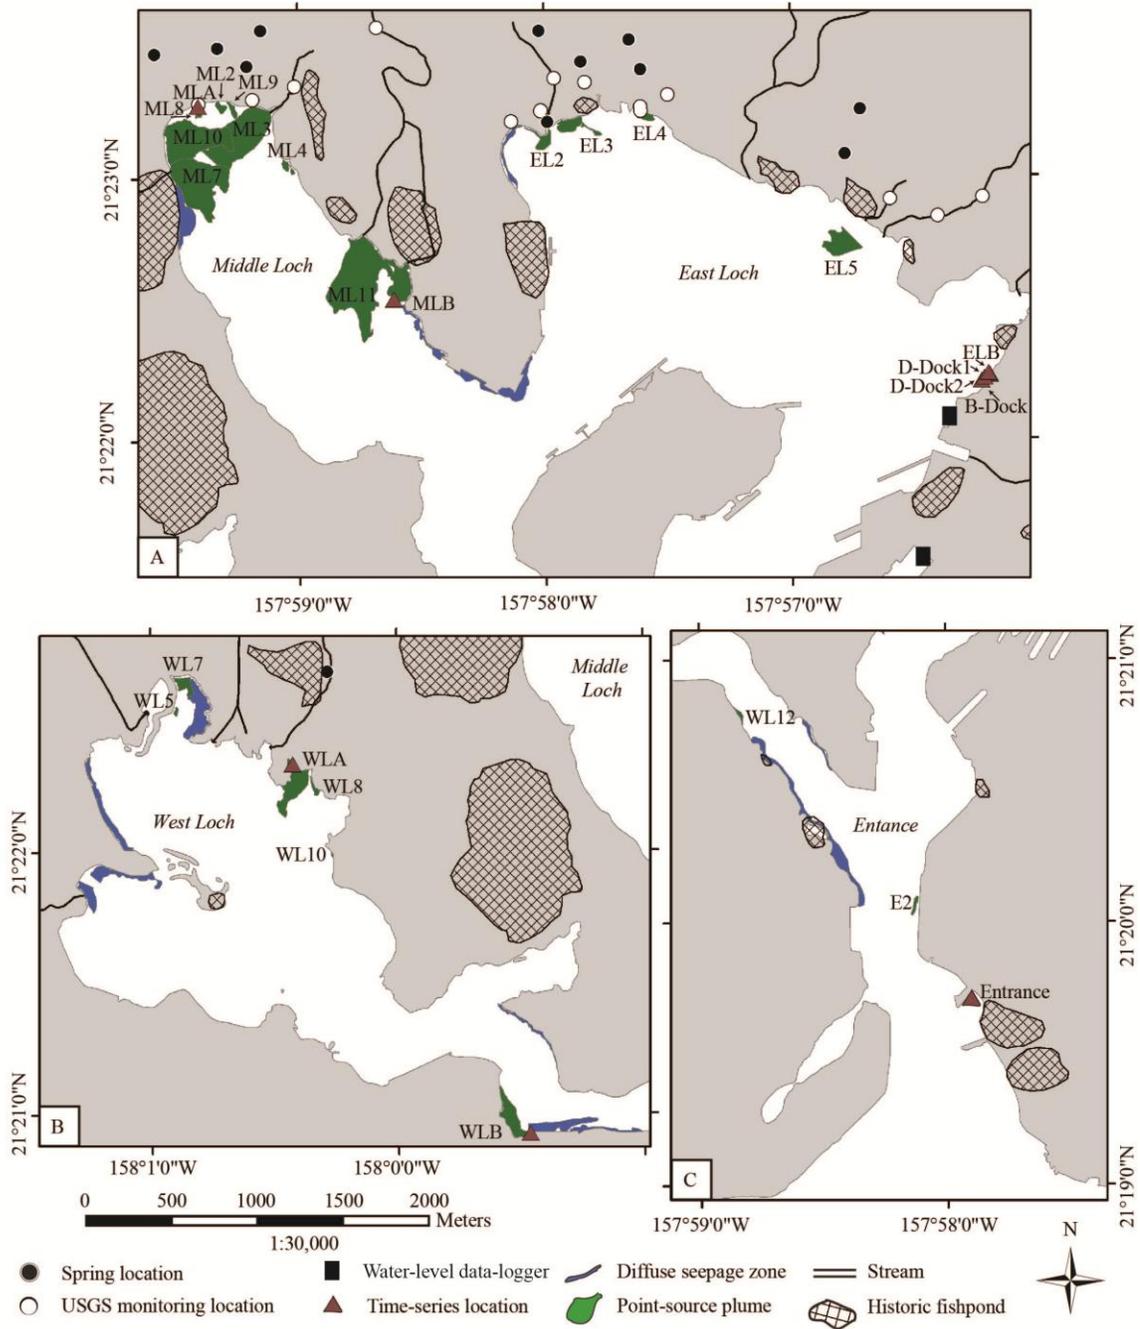

Figure 3.2: ^{222}Rn time-series (brown triangles) and water-level data-logger (black squares) locations. Twenty-five point-source plumes (green) and 13 diffuse seepage zones (blue) identified in the sea-surface temperature maps are also shown. The three point-source plumes at Rainbow Bay Marina are hidden by the time-series symbols. References for spring and historic fishpond locations are provided in the caption for Figure 3.1.

detector (RAD-7; DurrIDGE Company Inc., Billerica, MA) was connected to an air-water exchanger that received water from a bilge pump. Time-series deployments were equipped with a 32 L/min bilge pump, while surveys of surface waters and surveys of the water column utilized a 235 L/min bilge pump (both pumps manufactured by Rule, Gloucester, MA). The air-water exchanger facilitated evasion of ^{222}Rn from the water phase and into the air phase. Once in the air phase, ^{222}Rn entered the RAD-7 by a closed air loop (Lane-Smith et al., 2002).

While ^{222}Rn measurements were conducted, water temperature, salinity, conductivity, pH, and dissolved oxygen were measured by a multiparameter sonde (YSI 6600 V2-4, YSI 6920 V2, or YSI 600-XLM; YSI Inc., Yellow Springs, OH) or by a conductivity, temperature, depth sensor (CTD-Diver; Schlumberger Water Services, Houston, TX). All subsequent references to water quality parameters measured by either a multiparameter sonde or by a CTD-Diver refer to the exact parameters described above.

Tidal heights were determined by an ultrasonic water-level data-logger (Infinites USA, Inc., Port Orange, FL) that recorded data at 5-minute intervals. The water-level data-logger was deployed at one of the two locations identified on Figure 3.2, and compared to the National Oceanic and Atmospheric Administration (NOAA) tide gauge (1612340) positioned in Honolulu Harbor.

Wind speed data were obtained from the Honolulu International Airport weather station (WBAN #22521), located no more than ~15 km from Pearl Harbor. These data were reported at roughly one-hour frequencies.

Radon Stationary Time-Series Deployments

Eight ^{222}Rn time-series stations were deployed on stationary, floating platforms at or near point-source groundwater discharge locations throughout Pearl Harbor (Figures 3.2A-C). Two locations in Middle Loch, one location in East Loch, and two locations in West Loch were monitored during January 2010. Three locations were monitored near the same East Loch location as above from late February to early March 2010 (Figure 3.2A). One additional location, near the entrance to the harbor, was monitored in January 2010 (Figure 3.2C).

All time-series deployments continuously measured ^{222}Rn at 30-minute intervals for two to eight tidal cycles. Water for these measurements was collected ~20 cm below

the water's surface, regardless of tidal height. The multiparameter sonde was positioned ~20 cm below the surface and recorded data at 5-minute intervals.

We adopted the methodology described by Burnett and Dulaiova (2003) to build a non-steady-state ^{222}Rn mass-balance model for quantifying groundwater discharge fluxes. The model included the following ^{222}Rn source and loss terms: 1) input from in situ ^{222}Rn production through decay of its parent isotope ^{226}Ra , 2) input by groundwater flow, 3) input via diffusion from sediments, 4) removal through mixing with estuary waters, 5) removal by evasion to the atmosphere, and 6) removal due to radioactive decay. This model utilized differences in ^{222}Rn activity and salinity between ocean water and recently discharged groundwater to calculate fluxes of both components through defined coastal boxes. The coastal boxes were representative of groundwater-impacted areas for each time-series location.

^{222}Rn budgets for each time-series analysis were generated after measuring ^{222}Rn water activities, atmospheric ^{222}Rn (30 dpm/m³), water temperature, water salinity, water depth, air temperature, and wind speed. Data from the first analysis cycle (30 minutes) was ignored to allow the monitoring system to reach equilibrium. For all subsequent analysis cycles, excess ^{222}Rn was accounted for by identifying ^{222}Rn within the water column that was unsupported by ^{226}Ra . We used an offshore ^{222}Rn activity of 64 dpm/m³ calculated by Street et al. (2008) as well as 82 dpm/m³ (from stations H1, H3, and H4 in Street et al. (2008)) for the ^{226}Ra -supported activities of ^{222}Rn in water. We assumed an average tidal cycle length of 12 hours and 15 minutes and added an absolute viscosity calculation from Isdale et al. (1972) to the model. We used a proportionality constant of 0.5 (Macintyre et al., 1995) and molecular diffusion was calculated from Peng et al. (1974). ^{222}Rn inventories were normalized to tidal height and corrected for losses due to atmospheric evasion over each measurement interval. ^{222}Rn flux into estuary waters was estimated by calculating changes in ^{222}Rn inventory over time. We assumed minimum mixing losses to the inventory equaled maximum net negative fluxes. Summing minimum mixing losses, atmospheric evasion, and net fluxes for each measurement interval resulted in total ^{222}Rn fluxes. Total ^{222}Rn fluxes were then divided by the ^{222}Rn activity of the discharging water to calculate total water fluxes.

We scaled measured flux rates to each time-series location, by defining each platform's groundwater-impacted area. We calculated groundwater-impacted areas in two ways: (1) we used boat movements from the 2010 ^{222}Rn survey of surface waters to determine the distance the boat was from the shoreline, for one or multiple analysis cycles. We multiplied that distance by distance the boat traveled during the analysis cycle(s), and (2) we calculated the area within contoured plume boundaries observed on SST maps by the inflection-point technique described above.

To obtain volumetric fluxes, the groundwater-impacted area, calculated above, was multiplied by the thickness of the groundwater-impacted layer. Groundwater-impacted layer thicknesses were determined from depth profiles of the water column (surface of the water column to the sediment/water interface) collected in 2011 at the previous year's time-series locations (Figure 3.2). Groundwater-impacted layer thicknesses were measured during low tide conditions and matched to a similar tidal stage during each of the time-series deployments in 2010. The above match was a fixed point that was used to calculate corresponding changes in tidal heights for each analysis cycle relative to the record of the water-level data-logger.

Radon Surveys of Surface Waters

Surface-water surveys for ^{222}Rn of East Loch, Middle Loch, West Loch, and the entrance to the harbor were collected within three hours of low tide between 2 January and 8 January 2010. We operated a boat with a target speed of ≤ 5 km/h as close as possible to the shoreline. Actual travel speeds during the survey varied from stationary to 10 km/h. Average speeds were 3.2 km/h in 2010 and 2.6 km/h in 2011. For all surveys, the bilge pump was positioned ~ 20 cm from the water's surface. The RAD-7 was programmed to integrate ^{222}Rn measurements over 5-minute cycles. The multiparameter sonde was positioned ~ 20 cm from the water's surface and continuously logged water quality parameters at 30-second intervals. A GPSMAP 420S depth sounder and global positioning system (Garmin, Olathe, KS) continuously recorded depth, latitude, and longitude at 30-second intervals.

We combined ^{222}Rn , temperature, salinity, wind speed, depth, and latitude/longitude data into a ^{222}Rn box model for coastal surveys developed by Dulaiova et al. (2005) and modified by Dulaiova et al. (2010). Model parameters, including

activity of ^{222}Rn in air, pore-water, offshore water, and ^{226}Ra -supported levels of ^{222}Rn in the water were the same as described for the stationary platform model. In the surveying model, ^{222}Rn measurements were offset backward one analysis cycle from the multiparameter sonde, depth, and latitude/longitude data since the ^{222}Rn system took ~ 5 minutes to respond to changes in ^{222}Rn activity in the water. This offset also aligned measured activities to the physical location of the water cycling through the air-water exchanger and RAD-7 system, instead of the actual time when each analysis cycle was completed.

We converted all ^{222}Rn and salinity measurements from the surveys into groundwater discharge fluxes based on the following equations from Moore (1996):

$$Q_{SGD_{tot}} = \frac{A_{Rn_{cw}} * V}{\tau * A_{Rn_{gw}}} \quad (3.1)$$

and

$$Q_{SGD_{fresh}} = \frac{(S_o - S_{cw}) * V}{\tau * S_o} \quad (3.2)$$

where $Q_{SGD_{tot}}$ was total (fresh and saline) groundwater discharge and $Q_{SGD_{fresh}}$ was fresh groundwater discharge in m^3/d . $A_{Rn_{cw}}$ and $A_{Rn_{gw}}$ were ^{222}Rn activities in coastal water and groundwater in dpm/m^3 , respectively. S_{cw} and S_o were coastal water and offshore salinity. We assumed the offshore salinity equaled 35. V was the volume of the coastal water box in m^3 , and τ was the flushing rate of the volume of water considered in the calculation. Since we lacked flushing rates for our specific study period, we choose two different flushing rates for τ . We calculated $Q_{SGD_{tot}}$ and $Q_{SGD_{fresh}}$ using a tidal flushing rate (12 hours 15 minutes). We also used published flushing rates from Buske and Evans (1974), which were variable, and ranged from day(s) in the back of Middle Loch to as little as 30 minutes near the entrance to the harbor.

We calculated the volume of water in the coastal box for each analysis cycle in a multi-step process. First, we calculated the half distance between the previous ^{222}Rn and following ^{222}Rn measurements (Dulaiova et al., 2010) for all surveys of surface waters. Next, we calculated the area of the coastal box for one of two scenarios: (1) coastal boxes with no visible plumes on the SST map, or (2) coastal boxes with visible plumes on the SST map. For case 1, the perimeter of the coastal box was delineated by a line drawn perpendicular from the shoreline to the half distance location of the previous ^{222}Rn

measurement (side 1), continued to the half distance of the following ^{222}Rn measurement (side 2), drawn perpendicular from the end of the second half distance to the shoreline (side 3), and continued along the shoreline to the starting point (side 4). The area inside the box was then calculated based on the defined perimeter. For case 2, the perimeter of the coastal box was delineated by a line drawn perpendicular from the shoreline to the half distance location of the previous ^{222}Rn measurement (side 1), continued along the edge of plume boundary from the SST map until reaching the half distance of the following ^{222}Rn measurement (side 2), drawn perpendicular from the end of the second half distance to the shoreline (side 3), and continued along the shoreline to the starting point (side 4). The area inside the box was then calculated based on the defined perimeter. Our coastal boxes were, therefore, coastal polygons. For the depth component of the volume calculation, we assumed a groundwater-impacted layer thickness of 40 cm for the entire harbor, except in the back of Middle Loch where 0.85 cm was used (see discussion of ^{222}Rn surveys of the water column). The 40 cm depth represented the thickness of water sampled by the submersible pump, positioned ~ 20 cm below the water's surface.

Radon Surveys of the Water Column

^{222}Rn surveys of the water column were conducted to measure ^{222}Rn , temperature, salinity, and conductivity throughout the water column. All lochs of Pearl Harbor were surveyed between 5 January and 19 January 2011. At each depth-profiling location, a multiparameter sonde was first lowered through the water column to assess the depths where changes in temperature and salinity occurred. Three RAD-7s were then simultaneously deployed to monitor ^{222}Rn activities at three different depths in the water column. Each RAD-7 was programmed to measure at 5-minute cycles. One RAD-7 constantly monitored surface-water ^{222}Rn activities. Water quality parameters of surface-waters were also continuously measured by a multiparameter sonde at 1-minute intervals. The submersible pump for the second RAD-7 monitoring system was either placed at mid-depth in the water column, or where the preliminary temperature/salinity depth profile indicated different conditions from surface waters. The deepest pump, for the third ^{222}Rn monitoring system, was typically deployed at or near the seafloor. If the depth of the water column exceeded the hose length (9 m), the deepest pump was

suspended in the water column at ~9 m. Conductivity, water temperature, and absolute depths from the intermediate and deep water systems were measured at 30-second intervals using a CTD-Diver (described earlier) affixed to the end of each pump. All CTD-Diver conductivity measurements were converted to salinity using relationships derived by Williams (1986). Water column depth and geographic location were monitored at 30-second intervals by the GPSMAP 420S (described earlier). While the boat was transiting from one depth-profiling location to the next, the intermediate and deep pumps were brought to the surface to prevent impacting with submerged objects and dragging along the harbor's bottom. The pumps were lowered to their respective depths at the following depth-profiling location, after the preliminary temperature/salinity depth profile was completed.

The ^{222}Rn model and input parameters for all surveys of the water column were the same as the model used for surveys of surface waters. The first 5-minutes of ^{222}Rn data collected at each depth were ignored, as described above.

Results

Sea-surface Temperature Maps

All SST maps are shown in false color. In all SST maps, coldest temperatures are displayed as blue hues and warmest temperatures are displayed as red hues. SSTs varied from 24.2 to 27.8°C (e.g. Figures 3.5A-C, 3.9A-C).

On 12 June 2009, we collected thermal infrared data at a flight altitude of 1295 m. Our camera configuration gave a spatial resolution of 2.0 m at this altitude. On 17 July and 22 July 2009, we collected data at 2134 m, resulting in a spatial resolution of 3.2 m. During all flights, our target ground speed was 161 km/h, making consecutive images advance by 0.8 m on the ground at 1295 m flight altitude and by 0.5 m on the ground at 2134 m flight altitude.

Discrete Samples from Water Supply Wells and Coastal Springs

Fifteen samples of groundwater end-members (water supply wells and coastal springs) had temperatures that ranged from 20.20 to 24.06°C and salinities that varied

Table 3.1: Names, locations, sampling dates, temperature (Temp.), salinity (Sal.), measured groundwater ^{222}Rn activities and average ^{222}Rn activities used to estimate groundwater end-members for all ^{222}Rn models. Where available, a comparison to previous ^{222}Rn measurements by Hunt (2004) is made. All samples were collected in 2010.

from 0.00 to 1.90°C (Table 3.1). ^{222}Rn activities ranged from 78,235 to 591,361 dpm/m³ (Table 3.1).

Radon Stationary Time-Series Deployments

^{222}Rn activities, plume depths, and salinities through time for the six time-series analyses conducted in January 2010 are shown in Figure 3.3. ^{222}Rn activities varied from 2 to 50 dpm/L. Figure 3.4 shows measured ^{222}Rn activities and plume depths through time for the three time-series analyses conducted during February and March 2010.

Model parameters specific to each platform (average excess ^{222}Rn , average evasion of ^{222}Rn to the atmosphere, water depth, and plume area) are provided in Table 3.2. Table 3.2 also presents one to five estimates of groundwater fluxes for each of the nine time-series analyses. Multiple estimates were derived from varying surface area of the plume in the ^{222}Rn model, the survey of surface waters, and/or estimates of spring

flow from the USGS (http://hi.water.usgs.gov/studies/pearlharborsprings/data_phs09.html). Total discharge was calculated for nearly-complete to complete, even-numbered tidal cycles. Results for two tidal cycles, therefore, correspond to 49 ^{222}Rn analysis cycles at 30-minute intervals. In some instances, the time-series station was deployed for less than an even number of tidal cycles (at most, 2 hours 30 minutes short of the 12 hour 15 minute tidal cycle). Discharge estimates for these platforms are labeled as biased

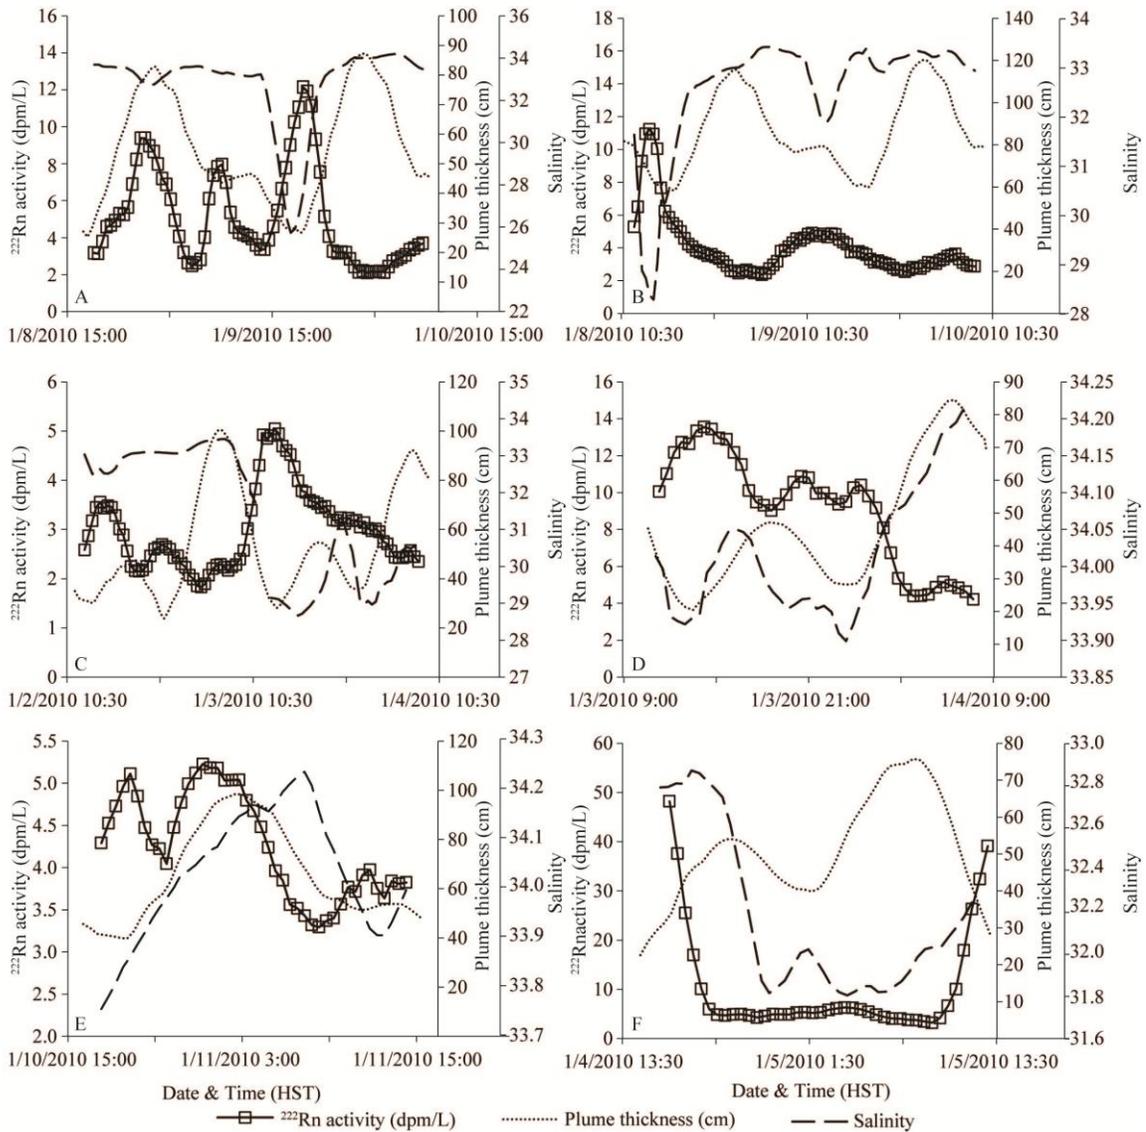

Figure 3.3: ^{222}Rn time-series results for: A) middle of Middle Loch (MLB), B) back of Middle Loch (MLA), C) back of West Loch (WLA), D) W4 pier in West Loch (WLB), E) entrance, and F) the east side of East Loch (ELB). Vertical and horizontal scales vary from by panel and are maximized to display the full range of the data. ^{222}Rn activities, salinity, and plume thicknesses are displayed as five-point moving averages.

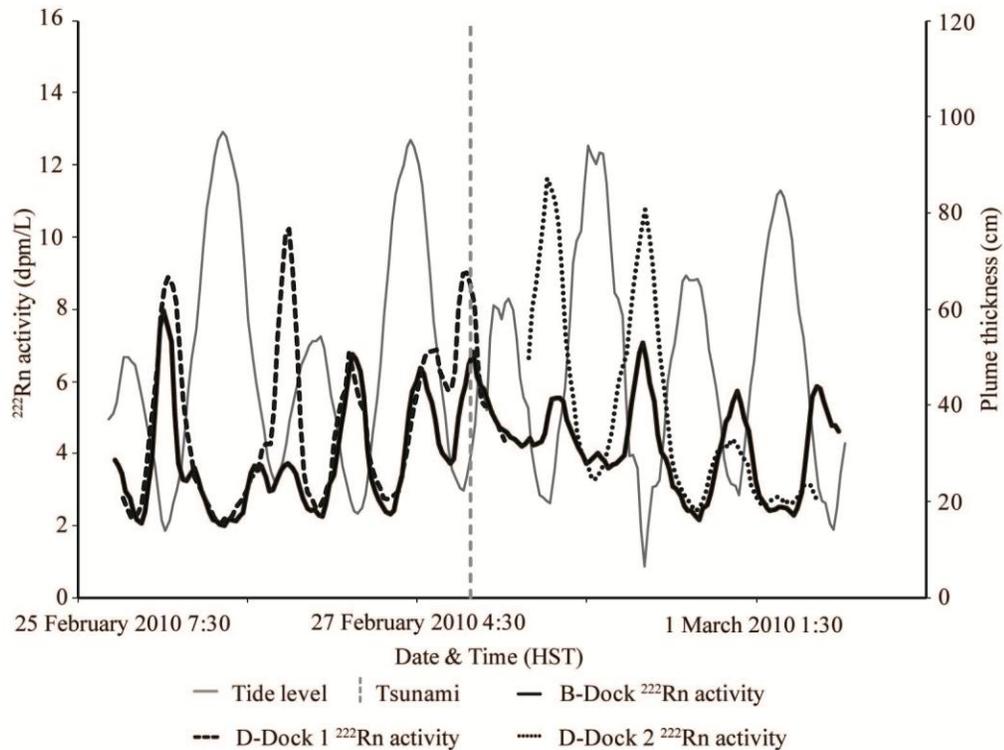

Figure 3.4: Three concurrent ^{222}Rn time-series results for stationary platforms deployed at Rainbow Bay Marina in East Loch from 25 February to 2 March 2010. The vertical line represents the time at which the first tsunami wave from the 27 February Chilean earthquake reached Pearl Harbor. ^{222}Rn activities, salinity, and depth are displayed as five-point moving averages.

toward high- or low-tide conditions (Table 3.2). Total discharge varied from $60 \text{ m}^3/\text{d}$ to $27,600 \text{ m}^3/\text{d}$ with one outlier at $177,200 \text{ m}^3/\text{d}$.

Radon Surveys of Surface Waters

^{222}Rn activities for the surface-water survey of Pearl Harbor conducted in January 2010 are shown in Figures 3.5A-C. The lines on Figures 3.5A-C delineate the path the boat took while travelling as close as possible to the shoreline. ^{222}Rn activities varied from 0.26 to 15.56 dpm/L in West Loch, 0.25 to 20.75 dpm/L in Middle Loch, 0.26 to 24.41 dpm/L in East Loch, and 1.30 to 23.28 dpm/L in the entrance to Pearl Harbor.

Figures 3.6A-C show total groundwater fluxes (calculated from eq. 3.1) to Pearl Harbor on a segment-by-segment of coastline basis for a tidal flushing rate. These groundwater fluxes were derived from the surface-water survey shown in Figures 3.5A-C. The shoreline length used to derive the units presented in Figures 3.6A-C was

Table 3.2: Groundwater-impacted layer depth, groundwater-plume surface area, method employed to calculate surface area, and groundwater discharge fluxes (rounded to the nearest lowest 100 m³/d, or to the nearest lowest 10 m³/d for fluxes <100 m³/d) for all nine time-series locations. Rainbow Bay Marina is abbreviated RBM. All TIR data were collected in 2009.

† Depth is reported as a fixed measurement that corresponds to a specific tide reported in the text. See the ²²²Rn Stationary Time-Series Deployments Discussion for more details.

* P is Pier and B is Bay

⁺ indicates that the discharge estimate is biased toward high tide and ⁻ indicates that the discharge is biased toward low tide. For two complete tidal cycles, n=49, for four tidal cycles, n=98.

described in the perimeter calculation (side 4) above. Total groundwater fluxes varied from 0.3 to 7.9 m³/m/d in West Loch, 0.1 to 42.8 m³/m/d in Middle Loch, 0.8 to 56.7 m³/m/d in East Loch, and 0.4 to 18.0 m³/m/d to the entrance of Pearl Harbor (Figures 3.6A-C). In contrast, flushing rates proposed by Buske and Evans (1974), generated groundwater fluxes that varied from 0.1 to 16.3 m³/m/d in Middle Loch, 0.3 to 41.5 m³/m/d in East Loch, and 0.1 to 138.9 m³/m/d to the entrance of Pearl Harbor. Flushing rates were unavailable for West Loch (Buske and Evans, 1974).

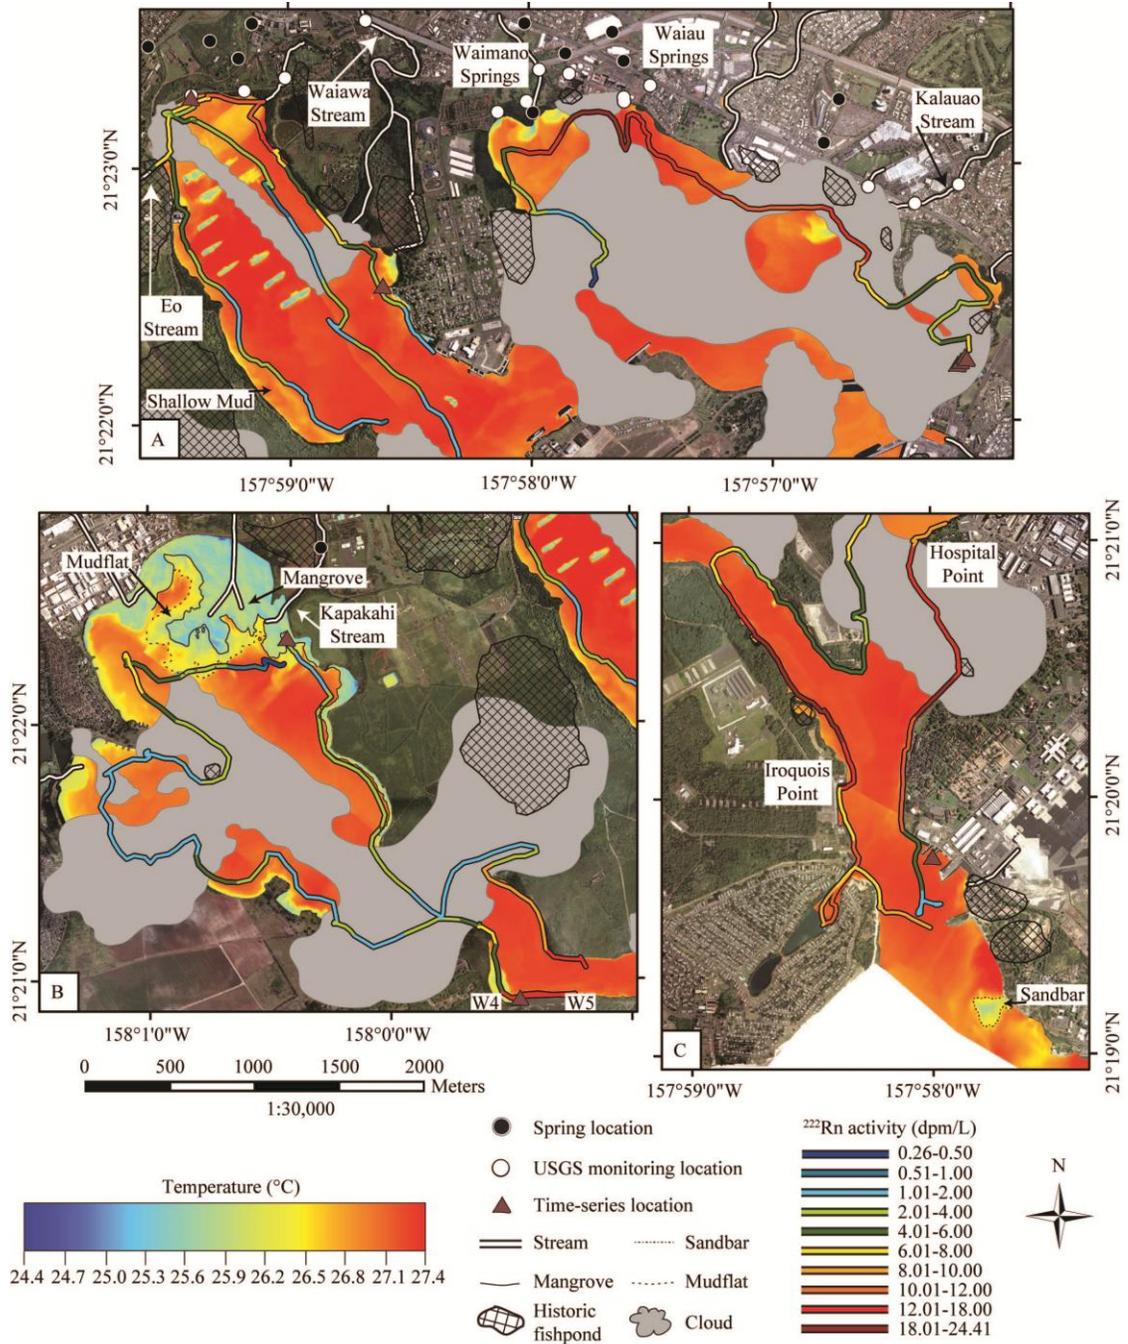

Figure 3.5: Surveys of surface waters for ^{222}Rn (colored lines) in Pearl Harbor superimposed on a sea-surface temperature (SST) map from 17 July 2009. A) Middle Loch (left side) survey collected on 8 January 2010 and East Loch (right side) survey collected on 4 January 2010, B) West Loch survey collected on 2 January 2010, and C) entrance to Pearl Harbor survey collected on 10 January 2010. Missing SST data are due to clouds. The seaward extent of mangroves (solid lines), mudflats (dashed lines), and sandbars (dotted lines) are delineated from water. ^{222}Rn activities are reported on a non-linear scale to better differentiate the data. References for spring and historic fishpond locations are provided in the caption of Figure 3.1.

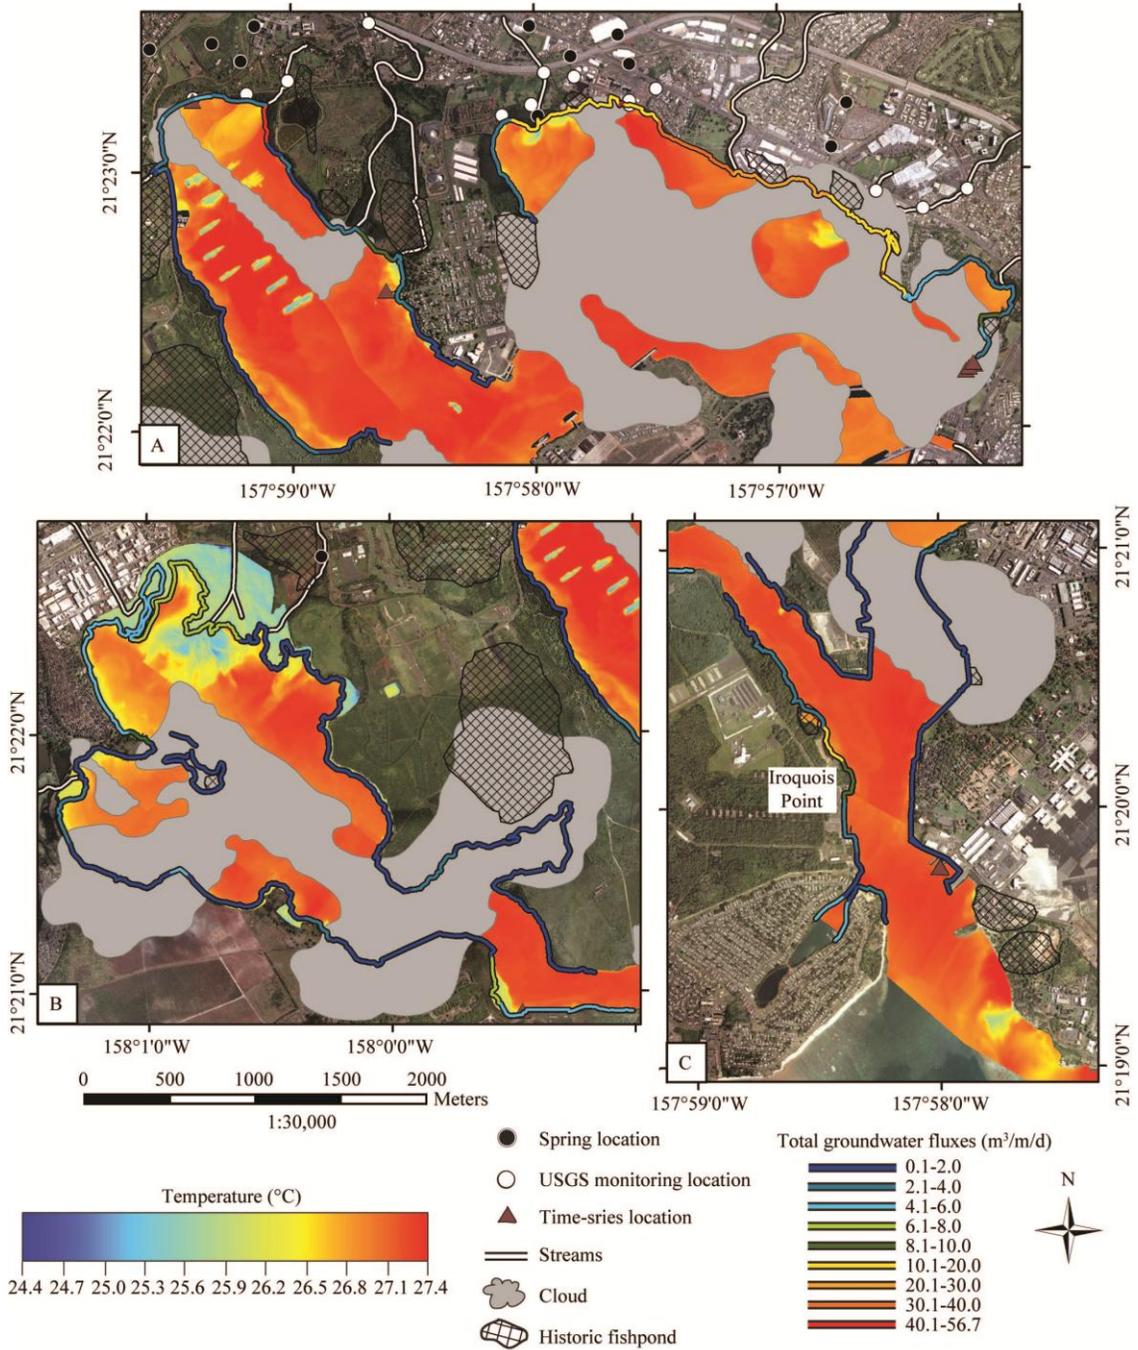

Figure 3.6: Total groundwater fluxes (m³/m/d) from the January 2010 surveys of surface waters: A) Middle Loch (left side) collected on 8 January 2010 and East Loch (right side) collected on 4 January 2010, B) West Loch collected on 2 January 2010, and C) the entrance to Pearl Harbor collected on 10 January 2010. Groundwater fluxes are displayed on a non-linear scale to better differentiate the data. Flux estimates are draped over the sea-surface temperature map from 17 July 2009. References for spring and historic fishpond locations are provided in the caption of Figure 3.1.

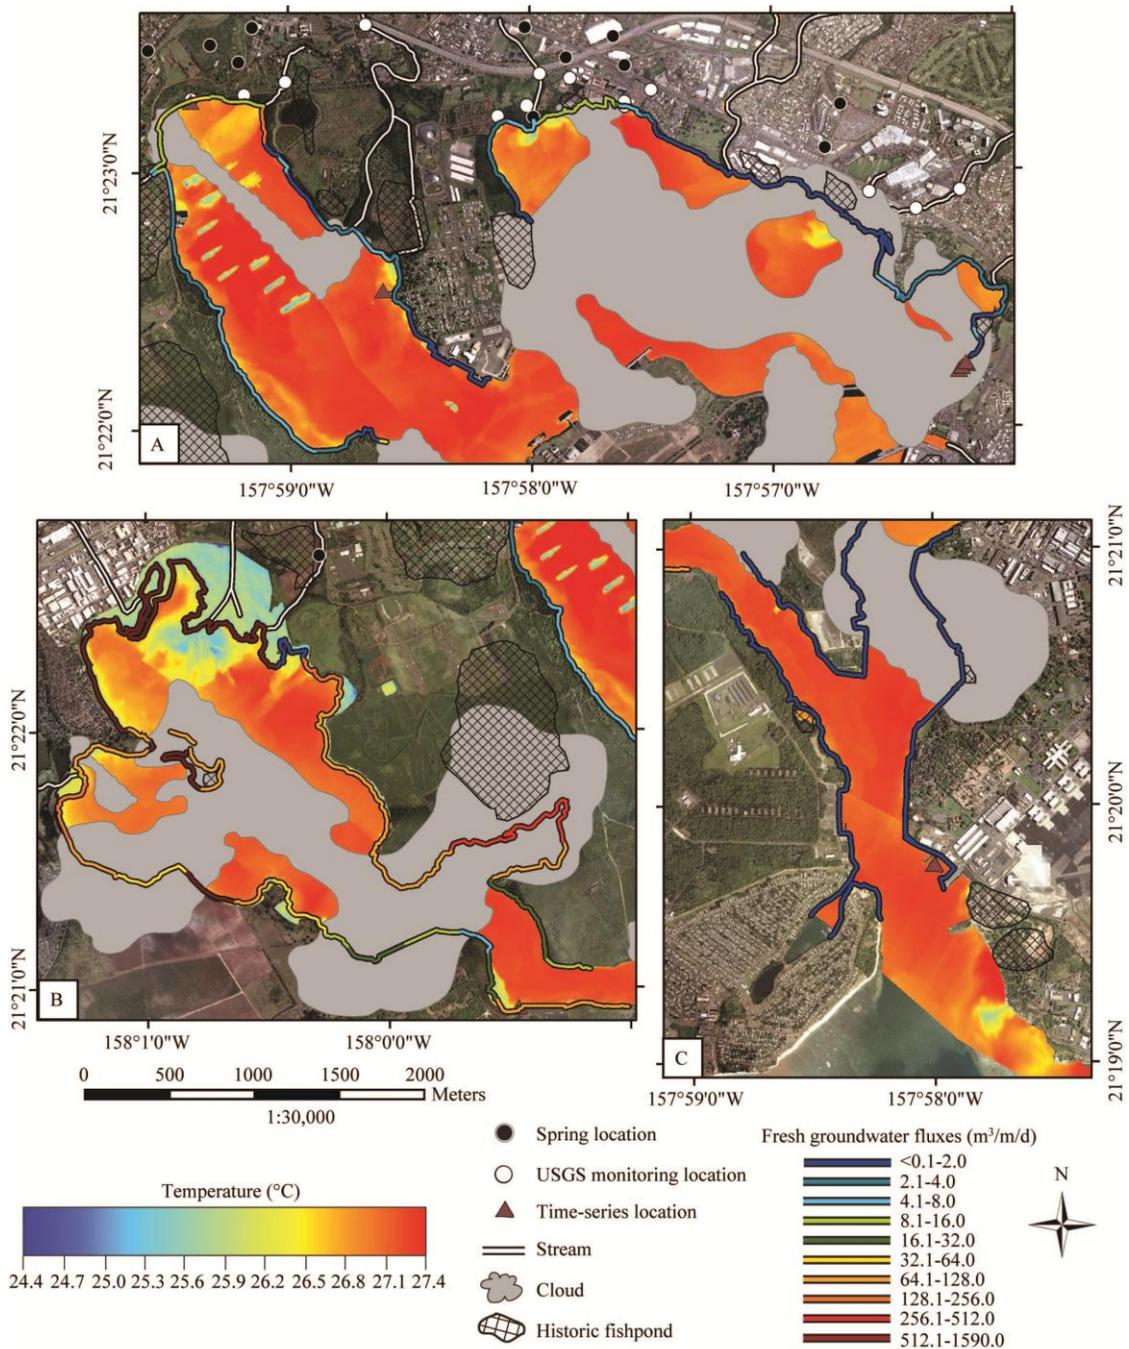

Figure 3.7: Fresh groundwater fluxes (m³/m/d) calculated by salinity balance from eq. 3.2 for the January 2010 surveys of surface waters: A) Middle Loch (left side) collected on 8 January 2010 and East Loch (right side) collected on 4 January 2010, B) West Loch collected on 2 January 2010, and C) the entrance to Pearl Harbor collected on 10 January 2010. Groundwater fluxes are displayed on a non-linear scale to better differentiate the data. Flux estimates are draped over the sea-surface temperature map from 17 July 2009. References for spring and historic fishpond locations are provided in the caption of Figure 3.1.

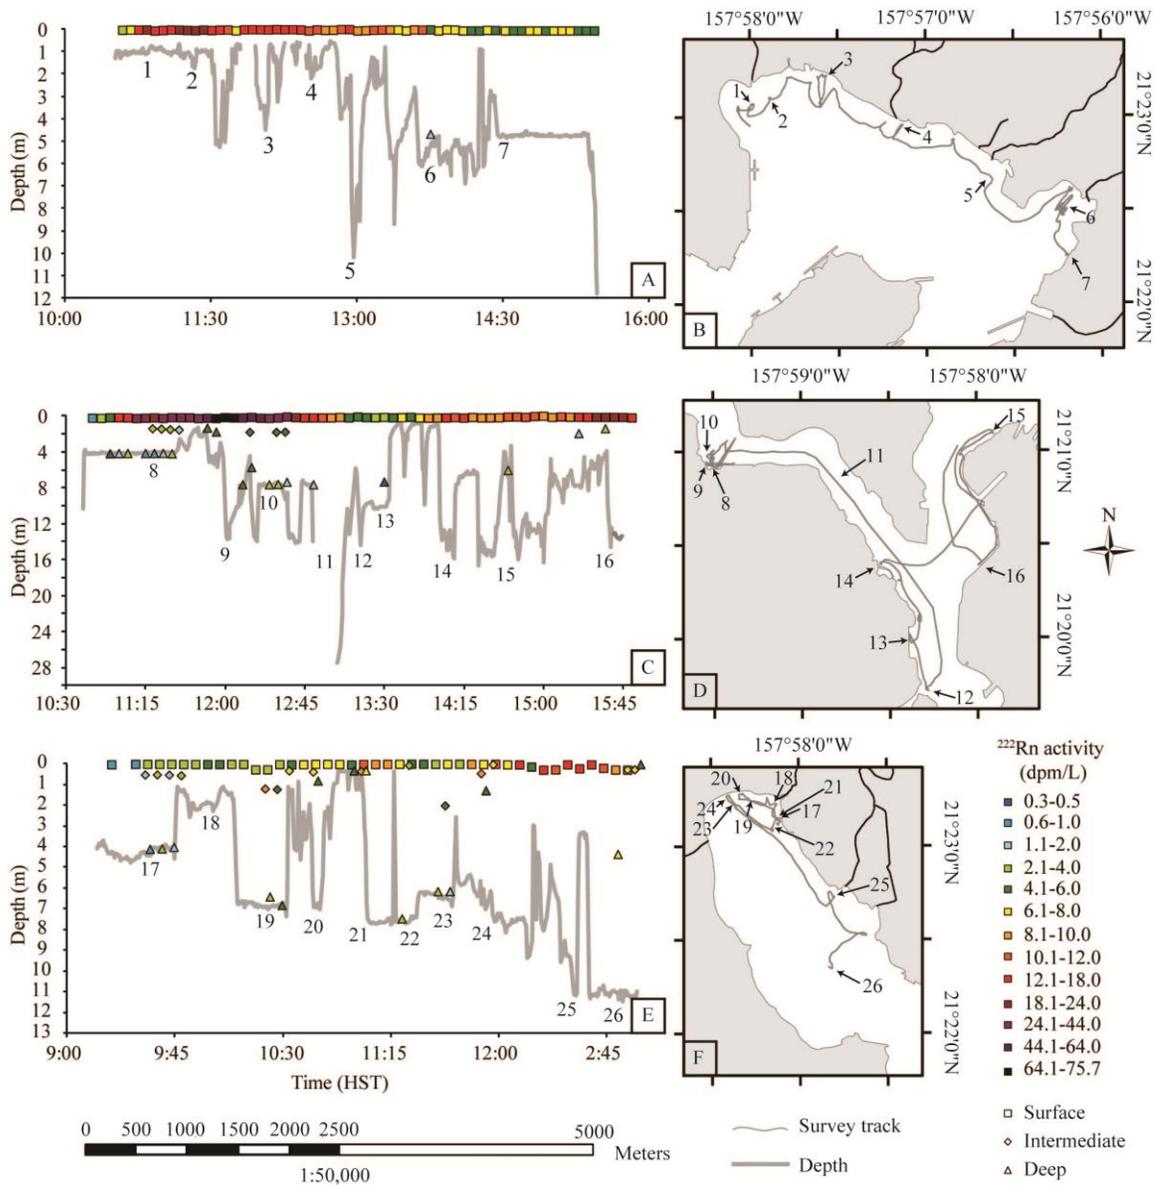

Figure 3.8: ^{222}Rn depth-profiling survey of: A and B) East Loch on 5 January 2011, C and D) West Loch and the entrance to Pearl Harbor on 7 January 2011, and E and F) Middle Loch on 19 January 2011. On panels A, C, and E, the solid gray line represents water-column depth recorded by the depth sounder. The boat path for each survey is shown as the gray line on panels B, D, and F. Station numbers are specified in the left panels and matched to their geographic location on the right panels. ^{222}Rn activities are displayed on a non-linear scale to better differentiate the data.

Figures 3.7A-C show fresh groundwater fluxes (calculated from eq. 3.2) to Pearl Harbor on a segment-by-segment of coastline basis. These groundwater fluxes were derived from the surface-water survey shown in Figures 3.5A-C. Shoreline lengths used

to calculate the results presented in Figures 3.7A-C were exactly the same as those used for the results shown in Figures 3.6A-C. Fresh groundwater fluxes varied from 0.1 to 1,590.0 m³/m/d in West Loch, 0.4 to 120.2 m³/m/d in Middle Loch, <0.1 to 19.0 m³/m/d in East Loch, and <0.1 m³/m/d to the entrance of Pearl Harbor. In contrast, for flushing rates proposed by (Buske and Evans, 1974), fresh groundwater fluxes varied from 0.2 to 37.2 m³/m/d in Middle Loch, 0.3 to 23.4 m³/m/d in East Loch, and 0.1 to 36.5 m³/m/d in the entrance to Pearl Harbor. Residence times were unavailable for West Loch (Buske and Evans, 1974).

Radon Surveys of the Water Column

Figures 3.8A-F show ²²²Rn activities of the water-column survey completed in January 2011. ²²²Rn activities varied from 0.3 to 75.8 dpm/L in West Loch, 0.5 to 14.0 dpm/L in Middle Loch, and 0.3 to 22.7 dpm/L in East Loch. Gaps in the intermediate and deep data shown in Figures 3.8A, 3.8C, and 3.8E occurred when the pumps were brought to the surface during transit. Gaps also occurred when insufficient time (< 10 minutes) was spent at a depth-profiling location.

Discussion

All remote sensing data, surveys of surface waters, and surveys of the water column were conducted within three hours of low tide. This timing was chosen because groundwater discharge should have been maximized due to a larger hydraulic gradient between the aquifer and the ocean. The groundwater discharge signal should also have been maximized at low tide because dilution of the estuary waters from intruding coastal waters during flooding tides was minimized. Time-series analyses were conducted over complete tidal cycles to capture the variability of groundwater discharge throughout a tidal cycle.

Infrared remote sensing data provide near-instantaneous, high-resolution (2.0 to 3.2 m) images of the estuary's SSTs, whereas the ²²²Rn survey data are averaged over 5-minute intervals and variable (1-100 m) spatial resolution. The ²²²Rn tracer, however, detects groundwater discharge below the water's surface, while the remotely sensed temperature data represents only the very top of the water's surface.

Aerial TIR Remote Sensing

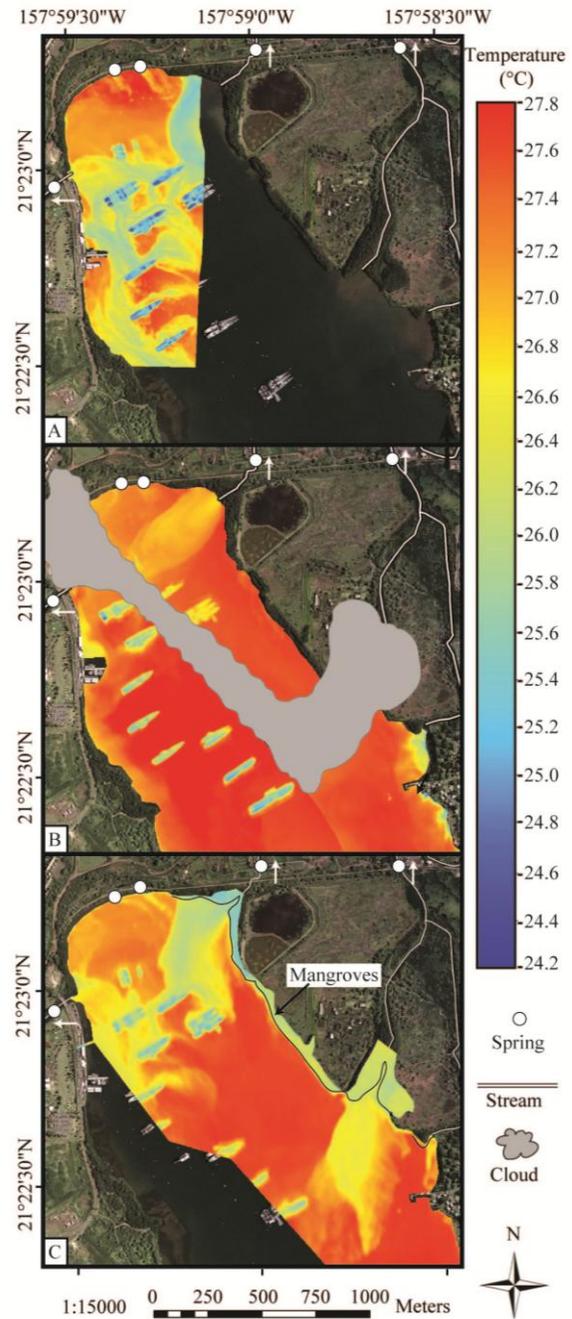

We collected thermal infrared data at night to avoid uneven solar heating of shallow coastal waters during daylight hours. We also collected data during clear to mostly-clear sky conditions to avoid clouds, which mask SSTs since the camera cannot see through them.

The aerial TIR remote sensing technique produced SST maps with 0.5°C accuracy and <0.1°C precision (see Chapter 2). The precisely known temperatures and high-resolution nature of the thermal infrared SST maps allowed us to categorize groundwater discharge into two groups: (1) point-source plumes, and (2) diffuse, non-point-source seepage. We define point-source discharge as water that emanates outward as a single, spatially well-defined plume or jet. Point-source discharge possesses distinguishable temperatures relative to the waters which surrounded it. Point-source plumes are also resolvable within the spatial resolution of our remote sensing configuration (2.0 to 3.2 m in this chapter). We define diffuse seepage as non-point-sourced flow that occurs as a broad-scale distribution with no discernible single input source. Diffuse flow results in a fairly large area of relatively uniform temperature-water, which is anomalously cold relative to the surrounding water.

Cold water temperatures in the TIR images (Figures 3.5A-C) represented one of several possibilities: drainage from subaerial springs, buoyant spring water from subsurface inputs, diffuse groundwater seepage, groundwater-fed streams, and non-groundwater-fed streams. Cold temperatures in the infrared images also corresponded to non-water features such as shallow mud (Figure 3.5A), mud flats (Figure 3.5B), mangroves (Figure 3.5B), and sandbars (Figure 3.5C). See Chapter 2 for a detailed discussion of these radiance interferences.

SST maps of Middle Loch, from three different dates (Figures 3.9A-C), demonstrate the dynamic nature of the estuary. Middle Loch has four groundwater-fed streams, at least two subaerial springs, three groundwater discharge locations at the beach, and two diffuse seepage zones. These distinct water masses and their mixing characteristics are evident in the SST maps (Figures 3.9A-C). Man-made objects or obstacles also influenced water movement and mixing in the estuary, for example, bifurcation of flow by the moored naval ships in the middle of the loch (Figures 3.9A-C).

Figure 3.9: Comparison of sea-surface temperature maps collected from Middle Loch, Pearl Harbor on: A) 12 June 2009 at 06:28 a.m. Hawaii Standard Time (HST); 1295 m altitude; 2.0 m spatial resolution, B) 17 July 2009 at 03:50 a.m. HST; 2134 m altitude; 3.2 m spatial resolution, and C) 22 July 2009 at 02:35 a.m. HST; 2134 m altitude; 3.2 m spatial resolution. Tidal conditions were +0.53 m for A, -0.04 m for B, and +0.17 m for C relative to mean-lower low-water recorded at the Honolulu tide gauge (1612340). All images are displayed at the same map scale and same temperature scale. Cold rectangular objects near the middle of the loch are moored naval ships. All streams are spring-fed; spring locations beyond the viewable area of the image are indicated by a white circle with a white arrow adjacent to the symbol. Panel C includes cold temperature mangroves, which are delineated from water by a solid black line. →

We used the inflection-point technique and the SST maps shown in Figures 3.5A-C and Figures 3.9A-C to delineate at least 25 distinct groundwater point-source locations (green polygons in Figures 3.2A-C) and 13 diffuse-seepage areas (blue polygons in Figures 3.2A-C). These calculations represent minimum values since clouds created gaps in the SST maps. Surface-plume areas varied in size from 230 to 160,240 m² (Table 3.2), while diffuse-seepage areas varied from 5,130 to 47,304 m². Point-source plumes were concentrated near well-known subaerial spring locations (e.g. Stearns and Vaksvik, 1935) such as those near the northwest corner of East Loch associated with the Waiiau and Waimano spring complexes (Figure 3.5A). Plumes were also visible at the mouths of spring-fed

streams like the Kalauao Stream in East Loch (Figure 3.5A) and Waiawa and Eo Streams in Middle Loch (Figure 3.5A). The diffuse-seepage zones were predominantly narrow, shore-parallel areas that had lower water temperatures than nearby coastal waters as shown in Figures 3.2A-C, which can be compared to Figures 3.5A-C.

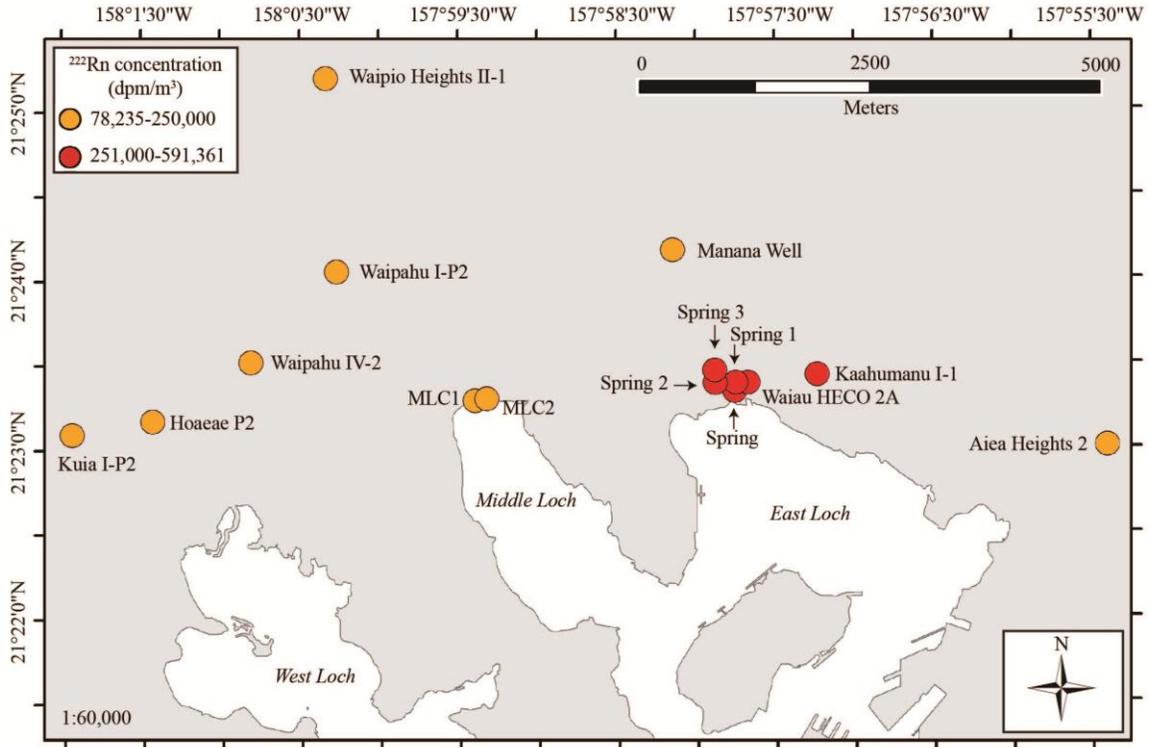

Figure 3.10: ^{222}Rn activities of groundwater end-members. The highest end-member activities (red circles) occur near the Waiau and Waimano spring systems shown on Figure 3.1.

Discrete Samples from Water Supply Wells and Coastal Springs

Groundwater temperatures in Southern Oahu vary from 20 to 25°C and are principally determined by the cool, atmospheric temperatures of the water’s mountainous areas of recharge (Visher and Mink, 1964). As groundwater travels toward the coast, it warms very little (Mink, 1964). This contrasts with coastal water temperatures, which typically vary from 24 to 28°C. During our study, well temperatures varied from 20.20 to 22.42°C (Table 3.1). Spring samples had temperatures (20.22 to 24.06°C) intermediate between recharge temperatures and coastal water temperatures (Table 3.1).

Samples from water supply wells and coastal springs indicated two distinct groundwater end-members with respect to ^{222}Rn as shown in Figure 3.10. The ^{222}Rn activity ($390,806 \pm 135,370$ dpm/L; $n=6$) of the fresh discharge from the Waiau and Waimano Spring systems was distinct from all other well and spring sources sampled ($99,016 \pm 16,658$ dpm/L; $n=9$; Table 3.1). Measured ^{222}Rn activities from all well samples were similar to their respective down-gradient subaerial springs. Two of the sampled wells were analyzed for ^{222}Rn by Hunt (2004). The Waipio Heights 2-1 sample in this study ($78,235$ dpm/m³) was similar to the Hunt (2004) measurement ($88,800$ dpm/m³). Aiea Heights 2, on the other hand, had less agreement between the two measurements ($95,748$ dpm/m³ in 2010 and $206,460$ dpm/m³ in Hunt (2004)).

Radon Stationary Time-Series Deployments

The surface expressions of groundwater plumes were dynamic and varied with differing wind directions and velocities (Figures 3.9A-C). Surface expressions of groundwater discharge will also change with time, seasons, weather, and tidal conditions. We, unfortunately, do not have data regarding the specific configuration of groundwater plumes and water masses during our ^{222}Rn deployments, as multiple logistical considerations prevented simultaneous collection of TIR and ^{222}Rn data. We accommodated this uncertainty as well as the natural variability of the surface expression of groundwater discharge by utilizing all available infrared imagery and ^{222}Rn surveys of surface waters to calculate multiple estimates for groundwater-impacted areas (Table 3.2). These areas were then used to calculate multiple estimates for V in equations (3.1) and (3.2).

All flux estimates from the platforms were calculated for measurements of nearly-complete to complete tidal cycles to avoid biasing the results toward high- or low-tide conditions. Tidal heights were allowed to vary in the model with the assumption that the groundwater-impacted layer became thicker during flooding tides, as water mixed into the layer, and became thinner during falling tides. Groundwater-impacted depths do not necessarily reflect total depth of the water column at each time-series location. The results from the time-series analyses represent the average discharge over the entire measurement period. Most of our groundwater flux measurements were conducted in

January and should represent maximum flows due to the seasonal demand of the aquifer's water (least in winter months).

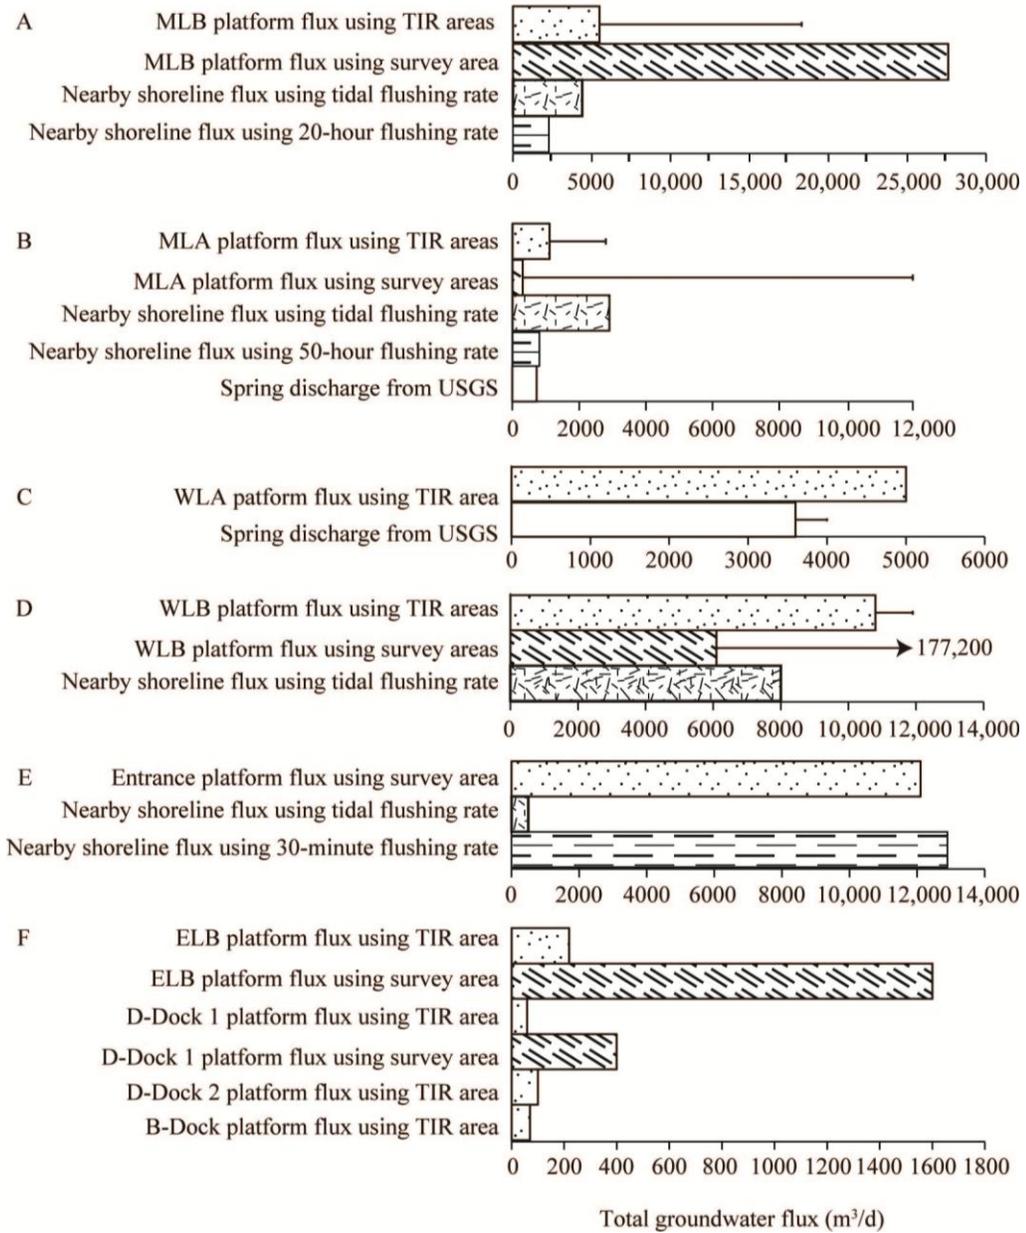

Figure 3.11: Horizontal bars represent total (fresh + saline) groundwater fluxes for each time-series location calculated by several methods. Error bars show a second groundwater flux estimate that utilized an additional data-set similar to the first. For example, the top bar for MLB represents fluxes calculated using the areas from SST maps collected on 17 July and 22 July 2009. The second bar for MLB represents the flux calculated using the area from the ^{222}Rn survey of surface waters. The bottom two bars for MLB represent fluxes of groundwater from the shoreline immediately adjacent to the platform location for the two flushing rate estimates.

In the discussion that follows, we provide flux estimates for groundwater discharge points identified and quantified based on the SST maps, ^{222}Rn time-series measurements, and ^{222}Rn surveys. Figure 3.11 illustrates the results from the combination of these techniques for the time-series locations in each loch. To quantify groundwater fluxes, we used the ^{222}Rn mass-balance of the time-series measurements and ^{222}Rn inventory mass-balance measured during the coastal survey. The area of groundwater plumes at each location, used for these calculations, was calculated from either SST maps (inflection-point technique) or ^{222}Rn surveys of surface waters (coastal box polygons). Note that the groundwater fluxes from the survey of surface waters and the survey of the water column are biased toward low tide, and should represent maximum flux estimates.

Middle Loch

The time-series analysis near the middle of Middle Loch (MLB; Figure 3.2A) was located ~275 and ~500 m from the mouths of two spring-fed streams and ~175 m from a diffuse seepage area. Salinity remained relatively constant between 32 and 34 but dropped to as low as 23.5 for ~12 hours during the middle of the deployment (Figure 3.3A). The low salinity occurred simultaneously with an increase in ^{222}Rn , reflecting intersection of MLB with recently discharged, less saline water.

The depth profile of the water column at MLB suggested a thin (~40 cm) groundwater-impacted layer at a tide-level of +0.09 m relative to mean-lower low-water (MLLW). We, therefore, used 40 cm for a corresponding tide-level during MLBs deployment. Calculated discharge rates ranged from 2,300 to 27,600 m^3/d (Figure 3.11A). The lower fluxes (2,300 to 4,400 m^3/d) from the shoreline adjacent to the platform may indicate that MLB received recently discharged water from beyond the area next to the platform.

The time-series analysis for the back of Middle Loch (MLA) was ~20 m from the nearest subaerial spring and ~140 m from the second nearest subaerial spring. It was also ~300 m from at least three coastal springs located at land/water interface, and ~500 m from the mouth of a spring-fed stream (Figure 3.5A). ^{222}Rn activities >4 dpm/L and salinities <16 near the beginning and middle of the deployment (Figure 3.3B) represented greater intersection of a recently discharged groundwater plume with MLA. We chose

the plume called MLA on Figure 3.2A, which was located closest to the time-series station (under time-series symbol on Figure 3.2A), for determination of the groundwater-impacted area. SST maps collected on multiple dates showed variable plume sizes (1,840 to 4,690 m²; Table 3.2). These plumes emanated from a spring that is monitored annually by the USGS. It has a fairly constant flow rate of ~730 m³/d (Figure 3.11B; http://hi.water.usgs.gov/studies/pearlharborsprings/data_phs09.html). Under near constant flow conditions, variable plume sizes must have reflected prevailing wind and tidal conditions as well as variable plume thicknesses.

During our 2011 survey of the water column at MLA, the groundwater-impacted layer was 85 cm at a tide-level of +0.04 m relative to MLLW, and extended to the bottom of the estuary. We used 85 cm for a corresponding tide-level during the time-series analysis. Calculated fluxes from ²²²Rn mass balance ranged from 800 to 12,000 m³/d (Figure 3.11B). The 50-hour residence time fluxes of 800 m³/d agreed with the 730 m³/d from the USGS (Figure 3.11B). However, we believe a tidal flushing rate better describes the data. At high tide, ²²²Rn activities decreased markedly on the time-series measurement and increased again at low tide, suggesting that the system was tidally flushed. Furthermore, the tidal discharge flux of 2,900 m³/d (biased to low-tide conditions) from the shoreline agreed with the 1,100 to 2,800 m³/d calculated from the time-series analysis (Figure 3.11B).

West Loch

The time-series location in the back of West Loch (WLA; Figure 3.2B) was located within a groundwater plume (yellow area on Figure 3.5B) that flowed through mangroves from the nearby groundwater-fed Kapakahi Stream. Kapakahi Stream has a USGS monitoring station located ~1,500 m upstream of its mouth with flow rates ranging from 3,600 to 4,000 m³/d (http://hi.water.usgs.gov/studies/pearlharborsprings/data_phs08.html). ²²²Rn activities at WLA fluctuated inversely with tide, increasing during ebbing tide and decreasing during flooding tide (Figure 3.3C).

By ²²²Rn balance, we calculated a discharge rate of 5,000 m³/d for this time-series (Figure 3.11C). Since the groundwater-impacted area within the mangroves could not be delineated, this flux represents a minimum estimate. The large size and relatively colder temperatures of the plume suggested that the area monitored by WLA was a main

receiving area for groundwater discharge from Kapakahi stream. Furthermore, since ^{222}Rn in recently discharged groundwater to the stream likely evaded to the atmosphere as the water travelled to the estuary, the calculated discharge from ^{222}Rn data would be a minimum flux. Despite this minimum estimate, the fluxes measured by ^{222}Rn mass balance were larger than the fluxes at the gauging station and provided evidence for groundwater inputs downstream of the gauging station.

The time-series station located inside of the U.S. Navy's W4 pier (Figure 3.5B) near the middle of West Loch (WLB; Figure 3.2B) was deployed in a location with no streams or historic fishponds, but was an area of cold groundwater flow (Figure 3.5B). The SST map showed a point-source groundwater plume immediately to the west of the pier, as well as a point-source groundwater plume that flowed laterally against the pier. These plumes coincided with some of the highest ^{222}Rn activities (13.7 dpm/L) measured in the harbor (Figure 3.5B). ^{222}Rn activities fluctuated with tidal level (Figure 3.3D), similar to the other West Loch time-series location. Salinity also correlated to tidal-level; it was higher at high tides and lower at low tides (Figure 3.3D).

We used a groundwater-impacted layer thickness of 40 cm, which was determined from survey of the water column at a tide-level of $\sim+0.17$ m relative to MLLW. Since we cannot conclusively say which one of the plumes was monitored by the stationary platform, both were considered in the ^{222}Rn model (Figure 3.11D). Groundwater flux estimates ranged from 6,100 to 13,840 m^3/d (Figure 3.11D).

Entrance

The time-series station deployed near the entrance to Pearl Harbor (Figure 3.2C) had fairly constant salinities (33.5 to 34.5) and exhibited no obvious correlation to tidal data (Figure 3.3E). No depth-profiling data were collected at this station, so a groundwater-impacted layer was assumed to be 40 cm thick at the lowest tide during the deployment. This should be a reasonable assumption given the fairly uniform surface-water salinities measured during the deployment. No TIR data were available for the time-series location, so the 2010 ^{222}Rn survey was used to calculate the groundwater-impacted surface area, and input into the ^{222}Rn mass-balance model. Calculated groundwater fluxes ranged from 500 to 12,900 m^3/d (Figure 3.11E). The largest fluxes

(12,100 and 12,900 m³/d agreed quite well and likely represented the amount of discharge to the area.

East Loch

Time-series analyses were conducted from the floating docks of Rainbow Bay Marina in East Loch (ELB; Figure 3.2A) in January 2010 and again during February and March 2010 (B-Dock, D-Dock 1, D-Dock 2; Figure 3.2A). For all deployments, we used a groundwater-impacted layer thickness of 40 cm at a tide-level of +0.15 m relative to MLLW. This depth was determined from the survey of the water column. During the January deployment, groundwater fluxes varied from 230 to 1,685 m³/d (Figure 3.11F). Water with ²²²Rn activities of 45-65 dpm/L intersected the platform at the beginning and end of the deployment, but not during the rest of the deployment (Figure 3.3F). This pattern likely reflected only partial intersection of the discharging water with the platform.

To obtain a better flux estimate of this plume, we deployed a longer time-series at the same location from the end of February to the beginning of March (D-Dock 1, Figure 3.2B). We deployed two additional time-series stations at Rainbow Bay Marina (D-Dock 2 and B-Dock), that intersected two other groundwater plumes identified in the TIR imagery. For these two additional platforms, one station was deployed for approximately half of the time and then moved to the second location. We therefore had two sets of simultaneously collected data from three different groundwater plumes that were located adjacent to each other (longest distance between the three plumes was ~80 m). Although the measured ²²²Rn activities at each platform differed, peaks and troughs in the activities occurred at the same time during the entire deployment (Figure 3.4), indicating that all three plumes behaved similarly. Calculated discharge rates for these three locations were 70 m³/d for B dock, between 60 and 400 m³/d for D-Dock 1, and 100 m³/d for D-Dock 2; Figure 3.11F). When combined together, these plumes contributed between 230 and 570 m³/d of total groundwater discharge to the harbor, assuming each platform independently monitored each of the plumes.

During the February and March deployment, a tsunami triggered by the 27 February 2010 Chile earthquake reached the Hawaiian Islands. The maximum water level change recorded by the deployed water-level data-logger was 15 cm (Figure 3.4).

There was no discernible impact on the groundwater flow as measured from the two simultaneously deployed ^{222}Rn - time-series stations; however, interestingly an “extra” ^{222}Rn peak corresponded to the first increase in water level.

Peterson et al. (2009) measured groundwater flow on the west side of the island of Hawaii from seven point-source locations. SGD for these sites ranges from 1,100 to 12,000 m^3/d , totaling 39,100 m^3/d . In comparison, our nine point-source measurements ranged from 60 to 18,300 m^3/d (Table 3.2) and totaled 46,200 m^3/d (average of multiple flux estimates per time-series station). Thus, recently discharged groundwater to Pearl Harbor (as detected by ^{222}Rn) is comparable to the major plumes measured from most of the west side of the island of Hawaii.

Figure 3.12 shows a strong ($r^2=0.98$, $n=12$) relationship between plume areas determined from TIR images and groundwater fluxes measured at the nine time-series locations. A weaker correlation exists for plume areas determined from ^{222}Rn surveys of surface waters and ^{222}Rn surveys of the water column ($r^2=0.70$, $n=9$; Figure 3.12). The strong relationship between plume areas and groundwater fluxes allowed us to estimate groundwater fluxes for all plumes visible on the SST maps that were not directly measured by ^{222}Rn time-series deployments (Table 3.3). We summed the regressed fluxes for plumes not measured in situ with averages of multiple estimates of plumes measured by time-series deployments. The total estimated flux of groundwater to Pearl Harbor was 333,380 m^3/d for all 25 plumes identified in the SST maps. Since we

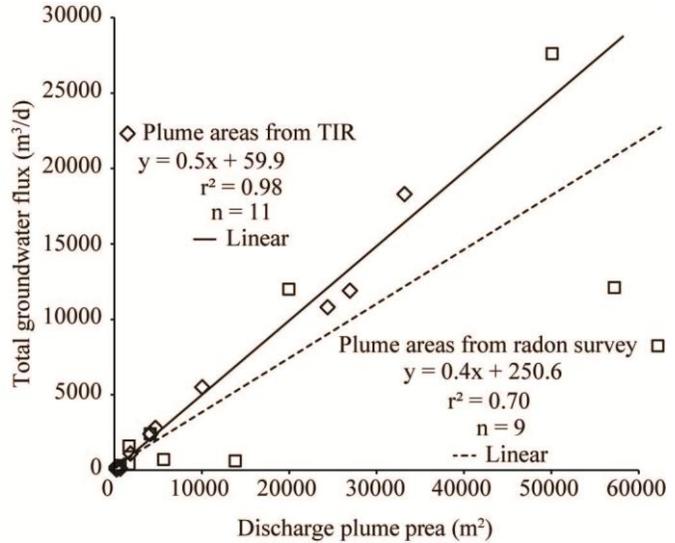

Figure 3.12: Correlation between groundwater fluxes calculated by ^{222}Rn mass balance for all nine stationary platforms and plume areas calculated from either sea-surface temperature maps (triangles) or surveys of surface waters (squares). All data points are from Table 3.2. The MLB discharge estimate of 177,200 m^3/d was excluded from the correlation.

targeted point-source flows for the time-series measurements, we cannot comment on a similar correlation between fluxes of diffuse discharge and surface areas.

Table 3.3: Point source plumes identified in the sea-surface temperature map and shown on Figures 3.2A-C. Plume areas were calculated from the temperature-inflection point technique, groundwater discharge fluxes were calculated from the strongest correlated regression in Figure 3.12, and groundwater discharge fluxes were calculated from the surveys of surface waters using a tidal residence time for comparison (where applicable).

Groundwater Fluxes from Radon Surveys of Surface Waters

All harbor water surveyed was above background ^{222}Rn activities (0.08 dpm/L). These activities indicated that all of Pearl Harbor's surveyed surface waters were impacted by recent groundwater inputs.

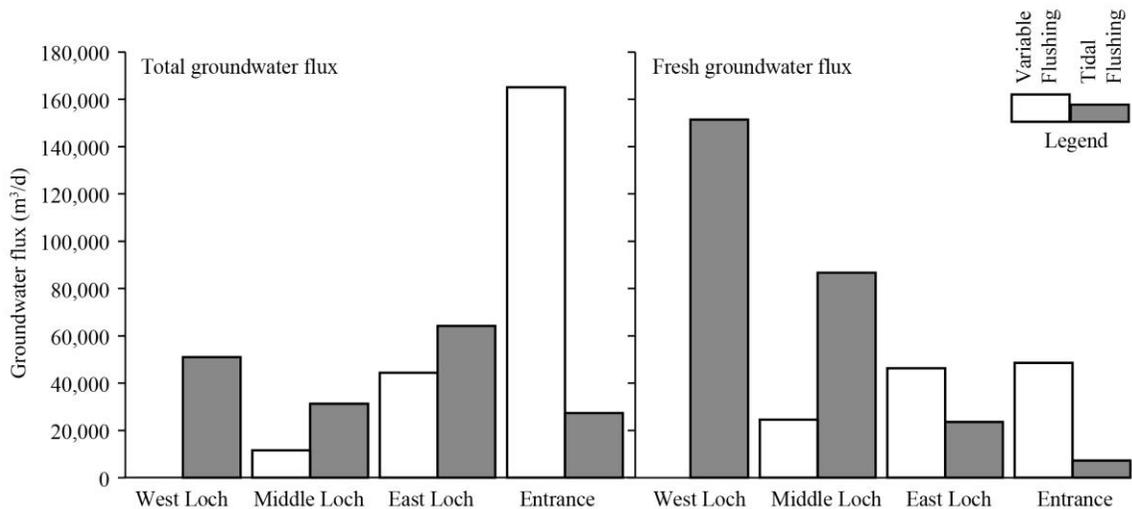

Figure 3.13: Comparison of total (fresh + saline) groundwater fluxes by ^{222}Rn mass balance to Pearl Harbor (left) and fresh groundwater fluxes (right) by salinity balance (eq. 3.2). Instances where fresh groundwater fluxes exceed total groundwater fluxes indicate either input of fresh water that is partially or fully degassed of ^{222}Rn , or input of stream water, which has negligible ^{222}Rn .

^{222}Rn was highest by the Waiiau and Waimano spring complexes near the northwest side of East Loch (Figure 3.5A). This also corresponded to the area with highest ^{222}Rn activities in groundwater end-members (Figure 3.10). ^{222}Rn was also elevated next to and across from the U.S. Navy's W4 and W5 piers (bottom right side of Figure 3.5B), near Hospital Point (Figure 3.5C), and near Iroquois Point (Figure 3.5C). The highest ^{222}Rn activities in Middle and East Lochs (Figure 3.5A) were adjacent to stream mouths and spring locations, indicating the presence of recently discharged groundwater (within the past 20 days based on a ^{222}Rn half life of 3.82 days X 5 decay cycles). Other areas of high ^{222}Rn that were not adjacent to streams corresponded to areas that have been dredged, for example near the W4 pier (Figure 3.5B), Hospital Point (Figure 3.5C), and Iroquois Points (Figure 3.5C). Areas of higher ^{222}Rn also occurred in

proximity to point-source and diffuse seepage zones identified in the TIR imagery from Figures 3.5A-C.

Using the variable flushing rates proposed by Buske and Evans (1974), calculated fluxes of total groundwater discharge to the harbor were: 11,600 m³/d to Middle Loch, 44,300 m³/d to East Loch, and 165,100 m³/d to the entrance (Figure 3.13). These estimates summed to 221,000 m³/d. No residence time data were available for West Loch. Flux estimates using tidal flushing rates, which assumed uniformly quick flushing of water for all areas of the harbor, resulted in 51,000 m³/d to West Loch, 31,200 m³/d to Middle Loch, 64,200 m³/d to East Loch, and 27,300 m³/d through the entrance to the harbor (Figure 3.13). Groundwater fluxes for a tidal flushing time summed to 173,700 m³/d. All of these fluxes represented minimum estimates since we lacked survey data for all shoreline areas, especially near the active U.S. Navy piers in East Loch. Furthermore, recently discharged groundwater to spring-fed streams had the potential for radon degassing, which would also cause the fluxes discussed above to be minimum estimates.

Figures 3.6A-C show that areas of highest total groundwater flow, as determined by ²²²Rn, included most of East Loch (Figure 3.6A) and the unnamed spring-fed stream near the back of the east side of Middle Loch (Figure 3.6A). Furthermore, areas of diffuse seepage that were identified on TIR images (Figures 3.2A-C), such as near Iroquois Point (Figure 3.6C), around the peninsula separating Middle and East Lochs (Figure 3.6A), and the northwest side of the back of West Loch (Figure 3.6B), typically exhibited greater fluxes than areas lacking diffuse seepage zones.

The combination of cold temperatures from the TIR survey and high ²²²Rn activities from the ²²²Rn survey of surface waters confirmed that many spring-fed streams (e.g. Kalauao Stream in East Loch; Figure 3.5A) contributed at least some amount of recently discharged groundwater that was not degassed of ²²²Rn. However, some spring-fed streams (especially those in West Loch; Figures 3.6A-C) contributed water that was partially or fully degassed of ²²²Rn. Runoff and drainage from each stream's watershed should have been naturally low in ²²²Rn, and would not have been detected by the ²²²Rn surveys.

Using the variable flushing rates proposed by Buske and Evans (1974), calculated fluxes of fresh groundwater discharge to the harbor were: 24,500 m³/d to Middle Loch,

46,300 m³/d to East Loch, and 48,600 m³/d to the entrance (Figure 3.13). These estimates summed to 119,400 m³/d. No residence time data were available for West Loch. Using tidal flushing rates, estimates of freshwater fluxes were: 151,300 m³/d to West Loch, 86,600 m³/d to Middle Loch, 23,600 m³/d to East Loch, and 7,200 m³/d through the entrance to the harbor (Figure 3.13). Fluxes calculated using tidal flushing rates summed to 268,700 m³/d. All of these fluxes represented minimum estimates since we lacked survey data for all shoreline areas.

Approximately 151,370 m³/d of freshwater entered West Loch compared to ~51,000 m³/d of total groundwater discharge detected by the ²²²Rn tracer. During the study period, Waikele Stream contributed, on average, ~35,500 m³/d of discharge (<http://hi.water.usgs.gov/>). This discharge should have contained negligible ²²²Rn. Unfortunately, the other streams entering West Loch were not monitored by the USGS. The disparity between the total groundwater and fresh groundwater fluxes measured during this study suggested that at least some of the water from Waikele Springs experienced ²²²Rn degassing as it travelled ~1600 m, before entering West Loch. In Middle Loch, the fresh groundwater flux (86,600 m³/d for tidal flushing) was greater than total groundwater flux (31,200 m³/d for tidal flushing). All of the streams flowing to Middle Loch were spring fed (Figure 3.9A), indicating that spring water was at least partially degassed of ²²²Rn. Some spring water reaching Middle Loch discharged at the beach, while other springs were located ~500 m from shore. In East Loch, fresh groundwater flux (23,600 m³/d for tidal flushing) was less than total groundwater flux (27,300 m³/d for tidal flushing), even near stream channels. Much of the recently discharged water likely experienced some degassing, but not to the same extent as West or Middle Lochs. East Loch, like Middle Loch, had several spring sources near the beach with several others ~500 m from shore.

Radon Survey of the Water Column

The ²²²Rn, temperature, and salinity/conductivity depth-profiling survey from January 2011 suggested that the water column had a uniformly thin groundwater-impacted layer (< 40 cm), with one exception near the back of Middle Loch. In this location, the groundwater-impacted layer was 0.85 cm thick and extended to the sediment/water interface. The survey also indicated isolated locations of groundwater

discharge from mid-depths into the harbor, for example, in Middle Loch at stations 19 and 24 (Figures 3.8E-F), despite continuously flowing subaerial springs near the shoreline. Conduits of submarine groundwater flow also existed at depth in the entrance to the harbor (stations 13 and 15, Figures 3.8C-D) and in West Loch (stations 8 and 10, Figures 3.8C-D). At station 8 (Figures 3.8C-D), for example, groundwater likely entered the harbor from or near the sediment/water interface in great enough quantity to generate a ~4 m thick water column of recently discharged groundwater. The location of this water mass suggested that it may have been possible for dredging activities to open conduits of groundwater flow. In Middle Loch, thick layers of water with uniform ^{222}Rn activity existed at stations 17, and possibly 23 (Figures 3.8E-F). All lochs also had isolated locations of slightly lower salinity water immediately overlying the sediment/water interface, indicating that brackish water seepage through bottom sediments may have been an important pathway for groundwater discharge to the harbor.

We observed groundwater discharging from the bottom of the harbor in West Loch. The discharge generated a detectable, lower-salinity plume at the surface of the water column, which was ~0.5 m thick. The plume was also visible on the SST map (WL5 in Table 3.3). Although the water was too shallow for a ^{222}Rn survey, this finding also demonstrated that groundwater entered the harbor through muddy bottom sediments. The regression from Figure 3.12 indicated that this small plume delivered $600 \text{ m}^3/\text{d}$ to the estuary, which was more than the individual plumes at Rainbow Bay Marina (Table 3.2), for example. Stearns and Vaksvik (1935) and Hunt (1996) speculated that such discharge locations likely occur through breaks in the caprock or where the caprock is absent or scant.

Multiple data sets provided a temporal comparison aspect to the study. Surveys of surface waters from January 2010 and 2011 typically showed similar spatial relationships. Areas of high ^{222}Rn in 2010 were also high in 2011, for example, area 2 on Figure 3.8A in East Loch varied from 18 to 24 dpm/L in 2010 (Figure 3.5A) as well as in 2011 (Figure 3.8A). One exception to similar ^{222}Rn activities occurred near the W4 pier, which had 75.7 dpm/L in 2011 (Figures 3.8C-D) and 15.0 dpm/L in 2010 (Figure 3.5B). The high 2011 activities may have resulted from eddying conditions, concentrating the recently discharged water in the bay, thereby building a strong ^{222}Rn inventory.

Alternately, the atypically high ^{222}Rn activities in 2011 may have been caused by greater groundwater discharge fluxes. Additionally, areas of high ^{222}Rn in 2010 and 2011 correspond to discharge plumes identified on the 2009 SST maps, indicating that the groundwater flow paths were active during the three years of this study.

Discharge from the Spring Complexes

Aquifer head has been shown to directly influence Pearl Harbor's spring discharge (Oki, 1998). Oki (1998) developed linear regression equations for discharge from each of the spring complexes in relation to water level in well 2256-10. We calculated the average head-level for this well for 2, 4, 8, and 10 January 2010 (our survey dates) as 4.94 m above sea level (USGS, 2010). We then applied regression equations from Oki (1998) and calculated a total spring discharge estimate of 289,860 m^3/d during our study period (61,678 for Waikele Springs, 74,234 for Waiawa Springs, 94,646 for Waimano and Waiiau Springs, and 59,302 for Kalauao Springs).

Although the springs did not strictly discharge freshwater, we compared the freshwater flux based on a tidal flushing rate (268,700 m^3/d) and the freshwater flux based on the variable flushing rate (119,400 m^3/d) to the spring discharge estimate (289,860 m^3/d). Our flux estimates were of the right order of magnitude. The spring complex discharge estimates and the estimates of total freshwater flux represented less than half of the volume of water indicated by historic spring discharge estimates of 800,000 to 832,000 m^3/day (Nichols et al., 1996).

Fishponds

Fishponds were once a common feature along Hawaiian Island coastlines, including Pearl Harbor. Prior to contact with western civilizations, it is estimated that the Hawaiians established over 350 operational coastal fishponds in the Hawaiian Islands (Kikuchi, 1976; Wyban and Wyban, 1989). In the 1920s, Pearl Harbor contained approximately thirty fishponds (Coles et al., 1997), but by the 1990s, most of its fishponds were destroyed (Englund et al., 2000).

Higher ^{222}Rn activities were generally found in proximity to former fishponds locations, especially along the northern side of East Loch (Figure 3.5A). The former fishpond near Hospital Point and the fishpond by Iroquois Point also corresponded to

areas of higher ^{222}Rn activities (Figure 3.5C) than the surrounding areas. A slightly weaker relationship may have been present for the large fishpond located between West Loch and Middle Loch (Figure 3.5A).

Conclusions

This work demonstrates the advantage of fully integrating thermal infrared and ^{222}Rn surface, depth, and time-series deployments. The thermal infrared and ^{222}Rn techniques complement each other, while independently assessing two different tracers: temperature and ^{222}Rn . The TIR and radon methods agree exceptionally well: areas of cold water in SST maps correspond with areas of higher ^{222}Rn activity. ^{222}Rn confirms TIR data interpretations in situations where the SST map contains temperature signals from features such as exposed beach sand, mud flats, and vegetation, which can look like cold groundwater discharge. The thermal infrared technique quickly assesses the distribution of groundwater discharge locations and scales over large areas of the water's surface, while the ^{222}Rn tracer detects groundwater below the water's surface that is invisible to the infrared technique.

The identification of diffuse seepage zones also benefited from the combined use of TIR and ^{222}Rn . Such seepage zones could have been misinterpreted using TIR data alone; however, correspondingly higher ^{222}Rn activities provided independent, supporting evidence of groundwater leakage to the harbor as diffuse flow.

In dynamic estuaries, water mass assessment is important, especially when using ^{222}Rn or salinity monitoring at time-series locations to ensure that the major discharging conduits are being monitored. Our study shows the importance of conducting water-column investigations where subaerial springs, submarine springs, and diffuse seepage zones are present. Unless flow is voluminous and buoyantly rises to the water's surface, seepage from mid-depths and from the sediment/water interface will not be detectable by aerial thermal infrared or the ^{222}Rn surveys of surface waters.

The strong relationship between plume areas and groundwater fluxes demonstrates a scientific advancement for the combined use of TIR and ^{222}Rn methodologies. We hypothesize that once a region has been mapped via TIR, and some certainty of groundwater fluxes has been established, regional up-scaling of coastal groundwater discharge is possible.

Future groundwater research in Pearl Harbor will require a more-detailed assessment of groundwater contributions to streams. If ^{222}Rn is used as a tracer, then a thorough investigation of ^{222}Rn degassing from spring-fed streams is necessary. Furthermore, the several occurrences of discharge from the bottom of the harbor that were found during this research warrant a more thorough investigation because these groundwater sources may be a large component of the groundwater budget to the harbor.

CHAPTER 4. QUANTIFICATION OF SUBMARINE GROUNDWATER-DERIVED NUTRIENTS TO PEARL HARBOR, HAWAII

Introduction

Submarine groundwater discharge (SGD) is a globally important source of terrestrially-derived nutrients to coastal ecosystems. Although SGD flux to coastal areas may be lower than surface water inputs, concentrations of dissolved constituents in SGD are often much higher than surface waters (Zektser et al., 2006). Discharge can, therefore, impact coastal ecosystems leading to eutrophication, harmful algal blooms, and shifts in the dominant flora and fauna of coastal waters (Dollar and Atkinson, 1992; Paerl, 1997; Miller and Ullman, 2004).

Several studies have shown that groundwater in the Hawaiian Islands can provide substantial dissolved nutrients to the uniformly low nutrient concentrations observed in offshore waters. For example, Dollar and Atkinson (1992) found that groundwater flowing underneath two golf courses on west Hawaii increased dissolved nitrogen and phosphorus fluxes by up to 229% and 400%, respectively. In Kahana Bay on Oahu, Garrison et al. (2003) found that total dissolved nitrogen and phosphorus fluxes by SGD were 200% and 500% greater than surface runoff fluxes, respectively. Johnson (2008) found that six SGD locations on the west side of Hawaii contributed approximately three times as much dissolved inorganic nitrogen as the Wailuku River, which is the largest river in the state of Hawaii. Street et al. (2008) calculated nutrient fluxes for west Hawaii, west Maui, and southern Molokai that were similar in magnitude to other estimates of nutrient fluxes from the Hawaiian Islands.

Pearl Harbor, which is located on the island of Oahu, is the largest estuary in the Hawaiian Islands and has the largest freshwater spring complex in the Islands (Englund et al., 2000). Despite the potential significance of dissolved nutrients, in both magnitude and environmental impacts, little is known about the quantity and distribution of dissolved nutrient loads to Pearl Harbor. Such knowledge is critical for understanding current and future effects of groundwater discharge and the dissolved nutrients it transports to the estuary.

The Pearl Harbor area has experienced a series of land-use changes, the most recent of which has been a shift from agricultural to urban zoning (Oki and Brasher,

2003). Discerning the sources of dissolved nutrients within the groundwaters as well as processes modifying the nutrients is crucial for evaluating how land-use influences nutrient loads in the groundwater.

We conducted this study to assess dissolved nitrate, phosphate, and silica loading to Pearl Harbor from groundwater sources. We also conducted this study to determine sources and transformations of nitrate along groundwater flow paths, and at groundwater discharge locations. An additional objective for this research was to locate areas where groundwater contributed the greatest nutrient loads to the harbor. We accomplished this by calculating nutrient fluxes for most of Pearl Harbor's shoreline.

Geologic Setting

Oahu, Hawaii (Figure 4.1) consists of the Waianae Mountains (Pliocene) and the Koolau Mountains (Pliocene and Pleistocene; Shade and Nichols, 1996). Koolau basaltic flows unconformably overlie Waianae basaltic flows (Stearns and Vaksvik, 1935), with flow interfingering likely at depth between the two mountain ranges (Hunt, 1996). The volcanic rocks are composed of numerous lava flows of varying thicknesses and

compositions. These flows are variable with respect to permeability, but have high permeability overall (Stearns and MacDonald, 1946). High permeability results from aa lava clinker zones, voids between lava flow contacts, cooling joints normal to flow surfaces, and lava tubes (Stearns and Macdonald, 1946).

All Hawaiian Volcanoes contain low permeability and low hydraulic conductivity dike complexes (Takasaki and Mink, 1985). Dikes are hydrologically important because

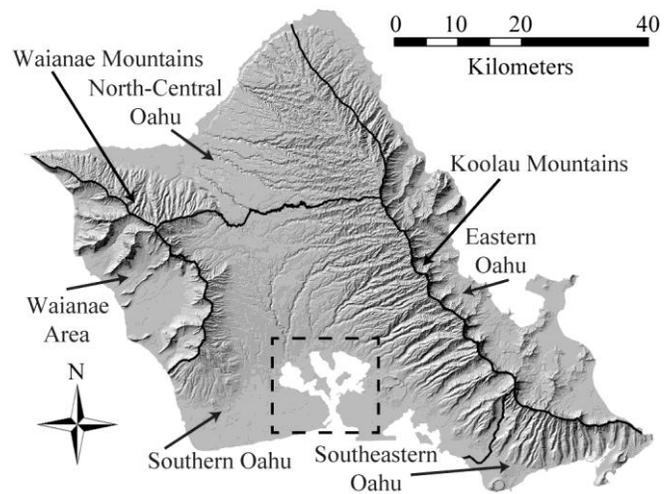

Figure 4.1: Hillshade of Oahu, Hawaii (Office of Planning, State of Hawaii; <http://hawaii.gov/dbedt/gis/hill.htm>) showing the five major groundwater flow systems. The groundwater flow systems are after Shade and Nichols (1996). The dashed box encloses Pearl Harbor.

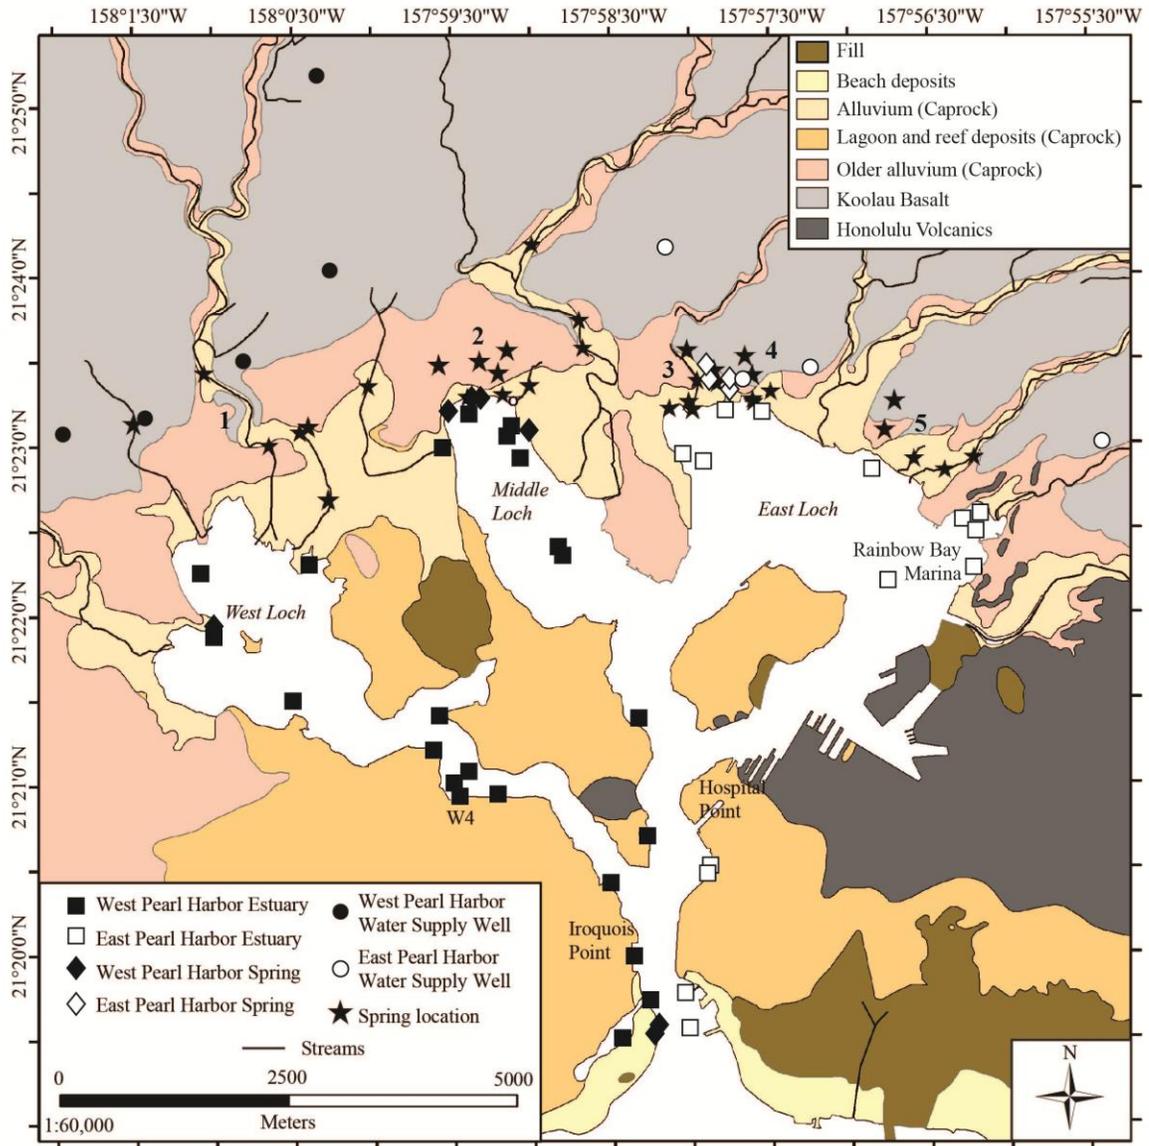

Figure 4.2: Generalized geologic map of Pearl Harbor (after Sherrod et al., 2007) showing the five spring systems. Each spring system is identified by numbers from west to east: 1) Waikele Springs, 2) Waiawa Springs, 3) Waimano Springs, 4) Waiau Springs, and 5) Kalauao Springs. Each spring system contains numerous subaerial springs (stars) that are located in the vicinity of the number identifier. Sample locations (squares, diamonds, and circles) are delineated by sample type. Spring locations are after Stearns and Vaksvik (1935).

they extend vertically and laterally for thousands of meters (Oki et al., 1999). These circumstances favor effective compartmentalization of the more permeable intruded rocks (Takasaki and Valenciano, 1969), creating isolated, but slightly leaky groundwater reservoirs (Hunt, 1996). These reservoirs are locally referred as high-level aquifers.

Fresh groundwater near dike-free coastal areas, on the other hand, exists in a freshwater lens that floats on denser saltwater roughly according to Ghyben-Herzberg principles. This water resides in the basal aquifer and ultimately discharges to the sea as submarine groundwater discharge (SGD).

Pearl Harbor (Figure 4.2) is an estuary that occupies a drowned river system. The drowned river system has been successively flooded and drained as a result of past sea-level changes (Stearns, 1985). Deposition of calcareous and non-calcareous marine sedimentary rocks, called caprock, over much of Pearl Harbor's coastal plain and valley mouth areas (Figure 4.2) ensued during lower sea-level stands (Stearns and Vaksvik, 1935).

Caprock varies greatly in composition, grain size, thickness, permeability, and porosity (Lau, 1962; Nichols et al., 1996). Caprock is aerially widespread and generally lies 150 to 300 m inland of the coastline (Lau, 1962). It can extend as far as 3 km into stream valleys (Lau, 1962). Caprock deposits are up to 300 m thick near the coast (Oki, 1998) and extend to 400 m below sea level off-shore of Pearl Harbor (Visher and Mink, 1964). Caprock overlies basaltic rock, subdividing basal water into several interconnected, but semi-independent water systems (Hufen et al., 1980). Fine-grained mud and marl in the caprock (Nichols et al., 1996) make it no greater than 1/500th as permeable as the underlying basaltic rock (Hufen et al., 1980).

Groundwater Occurrence

The primary source of groundwater to the Pearl Harbor area originates from rainfall over the Koolau Mountains (Figure 4.1), with smaller amounts from the Waianae Mountains (Hufen et al., 1980). Much of this recharge may be stored in high-level dike compartments before leaking to the basal freshwater lens. Rainfall infiltration in unconfined areas, proximal to the coast, also recharges the basal aquifer (Hufen et al., 1980; Nichols et al., 1996). In the past, irrigation-return flow augmented groundwater recharge in some areas, especially near central Oahu (Nichols et al., 1996). Irrigation-return flow has been found recently by Hunt (2004) in the volcanic aquifer.

The island of Oahu is divided into five major groundwater flow systems (Shade and Nichols, 1996; Figure 4.1). The Southern Oahu system contains Pearl Harbor, which contains a freshwater spring complex. Pearl Harbor's spring complex is divided into five

separate spring systems (Figure 4.2). Each spring system contains several subaerial springs that result from groundwater convergence in the basal aquifer along a narrow zone between the inland edge of the caprock and ~6 m above sea level (Stearns and Vaksvik, 1935; Visher and Mink, 1964). These artesian springs result from pressure generated by the confining caprock and represent overflow of the pressurized water from the upper part of the groundwater transition zone (Visher and Mink, 1964).

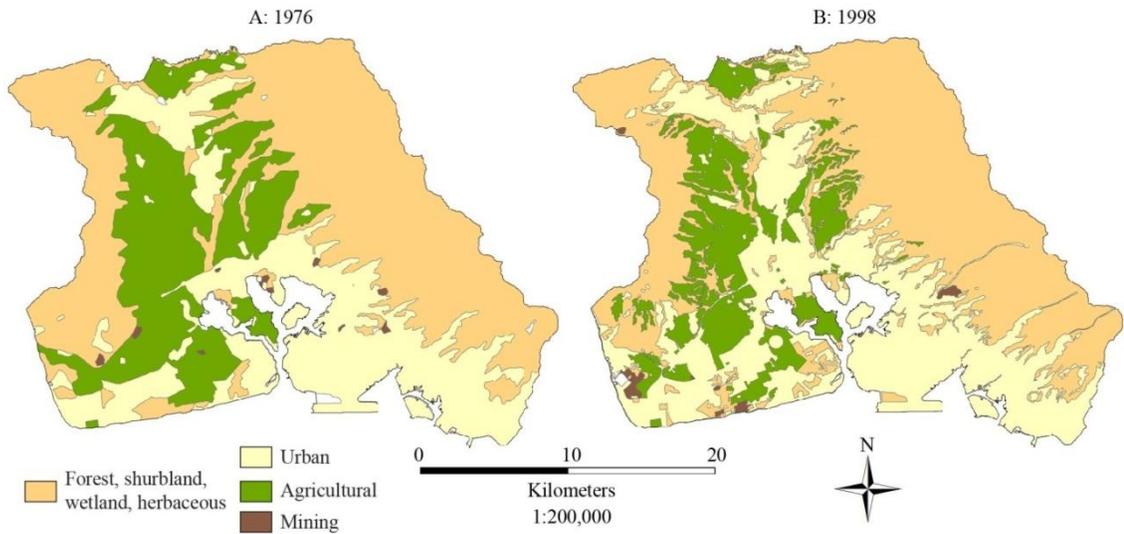

Figure 4.3: Comparison of land-use in the Southern Oahu sector in (A) 1976 (Santos, 1976) and (B) 1998 (Klasner and Mikami, 2003).

Subaerial springs are not traditionally considered a source of groundwater discharge to nearshore environments; however, past convention has included subaerial springs as a major groundwater source to Pearl Harbor. For example, Nichols et al. (1996) estimated that 70% of the natural groundwater discharge to Pearl Harbor occurred through the springs, with the remainder entering the harbor as diffuse flow. To maintain consistency with this classification scheme, we also classify subaerial springs as a source of groundwater to the harbor, but not a source of SGD to the harbor. True sources of SGD to Pearl Harbor include all submarine springs and diffuse seepage areas. Hunt (1996) hypothesized that true SGD flows into Pearl Harbor occur where the caprock is absent or scant. Lau (1962) and Visher and Mink (1964) hypothesized that SGD also

enters the harbor through the caprock in areas that only contain terrestrial sediments and where weathered basalt, marine sediments, and pyroclastic materials are absent.

Land-Use

The area surrounding Pearl Harbor has experienced a series of land-use changes as large-scale plantation-style sugarcane and pineapple agricultural fields have been slowly replaced by more urbanized land-use and diversified agriculture land-use (Oki and Brasher, 2003). The land-use map (Figure 4.3A) for the Southern Oahu flow system from 1976 (Santos, 1976), shows that the area was dominated by forested land (48%) followed by urban areas (29%), and agricultural uses (23%). This contrasts to the 1998 land-use map (Figure 4.3B; Klasner and Mikami, 2003), in which forested land remained at 48%, urban areas comprised 36%, and agriculture lands occupied 16% of the area. Overall, there has been a consistent pattern of more agricultural lands on the west side of Pearl Harbor and more urbanized lands on the east side of the harbor (Figures 4.3A-B).

Dissolved Inorganic Nutrient Sources

In Hawaii, all groundwater undergoes chemical modification as it flows from its recharge area toward coastal discharge zones. Groundwater obtains its dissolved inorganic nutrients from several sources. Virtually all silica and phosphate is derived from soil and rocks (Visher and Mink, 1964). Basaltic rock composition and rainfall intensity favor high silica removal rates during weathering (Hufen et al., 1980). As groundwater flows from dike-impounded aquifers toward the down-gradient basal-freshwater lens system, groundwater silica concentrations typically increase due to dissolution of volcanic rocks along the flow path (Visher and Mink, 1964). Nitrate, on the other hand, is derived from the atmosphere, plant residue leachate, fertilizers in agricultural areas, and sewage in urbanized areas (Visher and Mink, 1964).

The groundwater flow system's natural landscape and land-use practices likely influence the dissolved nutrient loads that are supplied to Pearl Harbor. The similar geology of the area will allow for assessment of how the predominantly agricultural land-use practices on the west side of Pearl Harbor compare and contrast to the predominantly urban land-use practices on the east side of the harbor.

Methods

Water Sampling

Seventy-five water samples of fresh and brackish groundwater, as well as estuary waters thought to represent end-member compositions were collected in January and February 2010 and in January 2011. Nine water supply wells operated by the City and County of Honolulu Board of Water Supply were sampled on 28 January 2010 using existing pumps in the wells. Six coastal springs were sampled on 8 January 2010 and 9 February 2010 by peristaltic pump (geotech, Denver, CO). Between 2 and 8 January 2010, three pore-water samples were collected using a 0.91 m long, 0.64 cm diameter push-point piezometer (M.H.E. Products, East Tawas, MI) connected to a peristaltic pump (described above). Twenty-seven water samples from the surface waters of Pearl Harbor were collected from 2 to 11 January 2010 and 16 additional surface-water samples were collected from 5 to 19 January 2011. An additional seven City and County of Honolulu Board of Water Supply wells and one urban spring located near eastern Oahu were sampled on 27 and 28 October 2010. All sampled locations were analyzed for dissolved inorganic nutrients: Si(OH)_4 , NO_3^- , NO_2^- , NH_4^+ , and PO_4^{3-} , as well as the nitrogen and oxygen isotopic composition of dissolved nitrate. Temperature, salinity, and specific conductivity were determined by multiparameter sondes (YSI XLM-600, YSI 6920 V2, or YSI 6600 V2-4; YSI Inc., Yellow Springs, OH) at the time of sample collection. Geographic positions were determined using a hand-held GPS receiver (Garmin eTrex, Olathe, KS) with 15 m accuracy.

Dissolved Inorganic Nutrients

Samples for dissolved inorganic nutrients were collected in 500 mL high density polyethylene (HDPE) bottles that were pre-cleaned with 10% v/v hydrochloric acid (HCl; 1.2 N) and triple-rinsed with distilled, de-ionized water. During sample collection, HDPE bottles were triple-rinsed with sample water, filled, and stored in the dark inside of a chilled cooler while in the field. Temperature and salinity of all samples were determined at the time of sample collection using a multiparameter sonde (described above).

Upon completing each day of field work, samples for dissolved inorganic nutrients were split from the 500 mL bottle into 60 mL HDPE bottles that were pre-cleaned exactly the same way as the 500 mL bottle. Samples for dissolved inorganic nutrients were filtered using 45 μ m GC-F syringe filters (Nalgene, part #190-9945) to remove particulate matter. Prior to filling each new sample bottle, the filter was pre-flushed with at least 10 mL of either distilled, de-ionized water or sample water to remove any nutrients retained by the filter during manufacturing. Each 60 mL HDPE bottle was triple rinsed with filtered sample water, filled with approximately 50 mL of filtered sample, and then frozen until analysis at the University of Washington's Marine Chemistry Laboratory.

The Marine Chemistry Laboratory uses a Technicon AutoAnalyzer AAII (UNESCO, 1994) for spectrophotometric segmented flow nutrient analysis. The lab's reported detection limits were 0.76 μ mol/L for Si(OH)₄, 0.08 μ mol/L for NO₃⁻, 0.01 μ mol/L for NO₂⁻, 0.07 μ mol/L for NH₄⁺, and 0.03 μ mol/L for PO₄³⁻. Uncertainties on blind duplicates of three samples, reported for two standard deviations, were \pm 76 μ mol/L for Si(OH)₄, \pm 0.6 μ mol/L for NO₃⁻, \pm <0.1 μ mol/L for NO₂⁻, \pm 0.2 μ mol/L for NH₄⁺, and \pm 0.9 μ mol/L for PO₄³⁻.

Nitrogen and Oxygen Isotopes of Dissolved Nitrate

Samples for nitrogen and oxygen isotopic analysis of dissolved nitrate were collected in 60 mL HDPE bottles that were pre-cleaned exactly the same way as the 500 mL bottles described above. During sample collection, the 60 mL HDPE bottle was triple-rinsed with sample water. Samples were kept in the dark in a chilled cooler while in the field and immediately frozen upon returning to the lab. Temperature and salinity of all samples were also determined at the time of sample collection using a multiparameter sonde (described above).

Prior to analysis, nitrite was removed from each sample following the procedures by Granger and Sigman (2009). Samples were analyzed at the University of Hawai'i Stable Isotope Biogeochemistry Laboratory. Approximately 40 nmol concentration nitrate-aliquots of sample water were added to vials containing *Pseudomonas chlorophus*. Following incubation, the $\delta^{15}\text{N}$ and $\delta^{18}\text{O}$ values of the nitrous oxide gas produced from nitrate using the "denitrifier" method (Sigman et al., 2001 and Casciotti et al., 2002) were

measured using the system described by Popp et al. (1995) and Sansone et al. (1997). Briefly, nitrous oxide gas was stripped from the reaction vial, cryofocused, separated from other gases using a CP-PoraBond Q 25 m X 0.32 mm X 0.5 μm capillary column (Varian Capillary Column, Santa Clara, CA, part number CP7351), and introduced into the carrier stream of either a Finnigan MAT252 or Finnigan MAT253 mass spectrometer through either a modified Finnigan GC-C1 or thermo-Finnigan GC-CIII interface.

We used replicates of National Institute of Standards and Technology NIST-3 and the University of Hawai'i (UH) NaNO_3 isotopic reference materials to normalize all isotopic results. NIST-3, an internationally recognized nitrate reference material, has an assigned $\delta^{15}\text{N}$ of 4.7‰ versus air N_2 (Bohlke and Coplen, 1995) and a reported $\delta^{18}\text{O}$ of 25.6‰ versus Vienna Standard Mean Ocean Water (VSMOW; Bohlke et al., 2003). UH NaNO_3 has a previously determined $\delta^{15}\text{N}$ of 1.03‰ versus air N_2 . At least one blank, four NIST-3 isotopic reference materials and two UH NaNO_3 isotopic reference materials were analyzed in each batch of twenty analyses. At least two samples were duplicated in every batch and all results are expressed in ‰ notation. Nitrogen isotopic values are reported relative to air and oxygen isotopic values are reported relative to VSMOW. The N and O isotopic ratios represent the mean of any replicate measurements. Standard and duplicate analyses for each batch of samples ranged from 0.5 to 1.3‰ for $\delta^{15}\text{N}$ and averaged 0.6 ± 0.1 ‰, 1SD, n=80. Standard and duplicate analyses for each batch of samples ranged from 0.6 to 2.6‰ for $\delta^{18}\text{O}$ and averaged 1.71 ± 0.7 ‰, 1SD, n=72.

Results

Salinity

All samples of surface waters from Pearl Harbor varied from 22.20 to 34.50, except for one sample that had a salinity of 8.0 (Table 4.1). Pore-water samples ranged from 22.00 to 35.80. Spring samples ranged from 0.00 to 22.00. Water supply wells from Central Oahu (Figure 4.2) had salinities that ranged from 0.14 to 0.37. Similarly, water supply wells from the eastern side of Oahu (Figure 4.4) ranged from 0.14 to 0.47 (Table 4.1).

Table 4.1: Sample names, geographic coordinates (WGS84), dates, temperature (Temp.), salinity (Sal.), and location (west Pearl Harbor or east Pearl Harbor). For estuary, pore-water, and spring samples, WL = West Loch, ML = Middle Loch, EL = East Loch, and E, TS, and HIT = samples collected from the mouth of the harbor. Except for the seawater samples, locations are shown on Figures 4.2 and 4.4. See discussion for classification of west (W) and east (E) Pearl Harbor samples.

Ave.	0.1	7	<0.1	0.1	0.4	4.3	N/A	N/A

^aN/A indicates that the sample was not analyzed for its nitrate isotopic composition because nitrate concentrations were too low for analysis or that averages of groups of samples were not calculated.

^bExcludes WL1-1-1 which has a N:P ratio of 865.8.

Dissolved Inorganic Nutrients

Dissolved silica (DSi) was highly variable (17 to 874 μmol/L) in the study area, but was always one- to two-orders of magnitude higher in estuary water than in typical offshore water (~1.5 μmol/L; Laws et al., 1999). Concentrations of nitrate were two orders of magnitude higher in groundwater (149.7 μmol/L) than estuary water (7.0 μmol/L), while phosphate was one order of magnitude higher in groundwater (5.4 μmol/L) than estuary water (0.3 μmol/L). Nitrite and ammonium were one and two orders of magnitude higher in estuary water than in the groundwater, respectively (Table 4.2).

DSi concentrations from water supply wells located in Central Oahu varied from 693 to 1243 μmol/L. Nitrate in these wells ranged from 20.7 to 300.7 μmol/L, NO₂⁻ was <0.1 μmol/L, NH₄⁺ was <0.1 μmol/L, and PO₄³⁻ varied from 0.4 to 10.5 μmol/L (Table 4.2).

DSi in the three pore-water samples ranged from 116 to 385 μmol/L and averaged 256±135 μmol/L, 1SD. Orthophosphate varied from 0.8 to 1.7 μmol/L and averaged 1.2±0.5 μmol/L, 1SD. Nitrate concentrations ranged from 0.4 to 0.6 μmol/L. Nitrite in

all pore-water samples was $<0.1 \mu\text{mol/L}$. Ammonium varied from 0.1 to $2.9 \mu\text{mol/L}$ (Table 4.2).

Springs had DSi that ranged from 284 to $1010 \mu\text{mol/L}$ and averaged $587 \pm 254 \mu\text{mol/L}$, 1SD, $n=9$. Orthophosphate in the nine springs varied from 0.1 to $2.9 \mu\text{mol/L}$ and averaged $1.7 \pm 0.8 \mu\text{mol/L}$, 1SD. Nitrate concentrations ranged from 0.4 to $38.0 \mu\text{mol/L}$ and averaged $17.6 \pm 13.4 \mu\text{mol/L}$, 1SD. Nitrite in spring samples varied from <0.1 to $1.0 \mu\text{mol/L}$ and averaged $0.2 \pm 0.3 \mu\text{mol/L}$, 1SD. Ammonium ranged from 0.6 to $12.9 \mu\text{mol/L}$ and averaged $2.7 \pm 3.9 \mu\text{mol/L}$, 1SD (Table 4.2).

Water from Pearl Harbor's surface had orthophosphate concentrations that averaged $0.3 \pm 0.4 \mu\text{mol/L}$, 1SD, $n=43$. By loch, orthophosphate was $0.4 \pm 5 \mu\text{mol/L}$, 1SD, $n=11$ for West Loch, $0.6 \pm 0.6 \mu\text{mol/L}$, 1SD, $n=10$ for Middle Loch, $0.2 \pm 0.2 \mu\text{mol/L}$, 1SD, $n=10$ for East Loch, and $0.1 \pm 0.0 \mu\text{mol/L}$, 1SD, $n=12$ for the mouth of the harbor. With the exception of WL1-1-1, which had a dissolved nitrate concentration of $106.3 \mu\text{mol/L}$, nitrate throughout the harbor's surface waters varied from not detectable to $33.7 \mu\text{mol/L}$. West Loch averaged $14.4 \pm 31.5 \mu\text{mol/L}$, 1SD, $n=10$, Middle Loch averaged $11.6 \pm 15.2 \mu\text{mol/L}$, 1SD, $n=10$, East Loch averaged $1.5 \pm 3.3 \mu\text{mol/L}$, 1SD, $n=10$, and the mouth of the harbor averaged $0.9 \pm 1.1 \mu\text{mol/L}$, 1SD, $n=12$ (Table 4.2). DSi was highly variable (16 to $874 \mu\text{mol/L}$) in the surface waters. DSi in West Loch averaged $108 \pm 72 \mu\text{mol/L}$, 1SD, $n=10$, Middle Loch averaged $286 \pm 302 \mu\text{mol/L}$, 1SD, $n=10$, East Loch averaged $103 \pm 138 \mu\text{mol/L}$, 1SD, $n=10$, and the mouth of the harbor averaged $33 \pm 14 \mu\text{mol/L}$, 1SD, $n=12$ (Table 4.2).

Nitrogen to Phosphorus Ratios

Nitrogen to phosphorus ratios varied from 11.7 to 54.8 for drinking water wells located in Central Oahu (Table 4.2). Wells sampled near eastern Oahu varied from 23.6 to 77.3. In contrast, pore and spring waters had smaller ratios that varied from 0.5 to 29.1 and averaged 10.1 ± 8.3 , 1SD, $n=12$. One estuary sample from West Loch (WL1-1-1) had a N:P ratio of 865.8:1. Excluding this outlier, the harbor averaged 16.0 ± 20.4 , 1SD, $n=43$. West Loch averaged 22.1 ± 14.7 , 1SD, $n=10$, Middle Loch averaged 24.7 ± 32.5 , 1SD, $n=10$, East Loch averaged 5.2 ± 5.3 , 1SD, $n=10$, and the mouth of the harbor averaged 12.8 ± 16.3 , 1SD, $n=12$ (Table 4.2).

Dissolved Nitrate Stable Isotopes

The results for dissolved nitrate isotopic analyses are reported from those samples that contained $>1.2 \mu\text{mol/L}$ of dissolved nitrate (minimum concentration required for the analysis). Of the 75 samples collected, 44 samples had nitrate concentrations suitable for the isotopic analysis. The nitrogen isotopic composition of dissolved nitrate in Pearl Harbor's estuary waters ranged from +11.2 to +71.6‰, while the oxygen isotopic composition varied from -0.1 to +12.1‰. Spring samples had $\delta^{15}\text{N}$ compositions that ranged from +10.0 to +17.5‰ and $\delta^{18}\text{O}$ compositions that varied from +3.5 to +11.9‰. The water supply wells in central Oahu had $\delta^{15}\text{N}$ compositions that varied from +3.4 to +14.0‰, while $\delta^{18}\text{O}$ compositions varied from +1.1 to +14.9‰. The water supply wells sampled from the eastern side of the island had $\delta^{15}\text{N}$ compositions that ranged from +7.5 to +16.7‰ and $\delta^{18}\text{O}$ compositions that varied from -0.1 to +14.8‰ (Table 4.2).

Discussion

Dissolved Inorganic Nutrients

In the Hawaiian Islands, silica is not greatly influenced by soil adsorption processes (Visher and Mink, 1964). Hawaiian soils do, however, have higher uptake and sorption capacities for phosphorus than for nitrogen (Fox, 1967, Chang and Young, 1977). Nitrate readily leaches through the soil zone and reaches the groundwater table (Soicher and Peterson, 1997). Phosphates have a high reactivity and therefore strong affinity to adsorb to particles Parfitt et al., 1975; McLaughlin et al., 1981). Phosphate is usually retained in the soils by goethite and other iron and aluminum oxides and hydroxides (Parfitt et al., 1975; McLaughlin et al., 1981; Barron et al., 1988). Furthermore, phosphorus has a low solubility in soils (Parfitt et al., 1975; McLaughlin et al., 1981). It is generally believed that phosphorous fertilizers have not significantly affected groundwater quality (Parfitt et al., 1975; McLaughlin et al., 1981). Since the coastal waters surrounding Oahu are oligotrophic, and because the Hawaiian Islands do not have extensive shelves with organic-rich sediments, only small fractions of dissolved silica, nitrate, and phosphate are derived from seawater (Visher and Mink, 1964).

We assumed that the water supply wells were representative of the terrestrial part of the aquifer and classified them as fresh, groundwater end-members. Measured DSi in

the water supply wells was typical of the Hawaiian Islands, and reflected interaction between groundwater and volcanic rocks (Laws et al., 1999). The MLC1 and MLC2 samples (Table 4.2) were collected from springs located just above the high-tide line in the back of Middle Loch. These springs had DSi concentrations that were similar to DSi concentrations measured in terrestrial water from the west side of the central Oahu region (Kunia 1 P-2, Hoaeae P-2, Waipahu IV-2, or Waipahu I-P2). DSi in these springs was much higher than any terrestrial sample from the east side of Pearl Harbor. We therefore assumed that all groundwater flowing into Middle Loch originated from the west side of Pearl Harbor and designated the west side as one terrestrial end-member of the harbor (Table 4.3). We likewise assumed that terrestrial samples from the east side of the harbor (Kaahumanu I-1, Manana Well, Waiiau HECO 2A, Aiea Heights II, and all Waiiau HECO springs) were representative of the groundwater end-member for the east side of the harbor (Table 4.3).

Table 4.3: End-member characteristics used in theoretical mixing lines for nutrient calculations and as end-members for the dissolved nitrate isotope discussion (see below).

End Member	Sal.	DSi ($\mu\text{mol/L}$)	PO_4^{3-} ($\mu\text{mol/L}$)	NO_3^- ($\mu\text{mol/L}$)	NO_2^- ($\mu\text{mol/L}$)	NH_4^+ ($\mu\text{mol/L}$)	$\delta^{15}\text{N}$ ‰	$\delta^{18}\text{O}$ ‰
West Pearl Harbor (n=5)	0.20	1093	8.6	240.5	<0.1	<0.1	5.4	3.5
East Pearl Harbor (n=8)	0.27	683	1.7	29.8	<0.1	0.6	11.9	6.5
Estuary (n=4)	32.90	52	0.2	2.8	0.1	0.5	19.8	9.2
Seawater (n=5)	35.14	8	0.1	<0.1	0.1	0.3	N/A	N/A

Although phosphates from fertilizers are generally not believed to greatly impact the groundwater, higher phosphate concentrations in groundwater from the west side of the harbor (compared to the east side) suggested that agricultural processes did augment the phosphate supply to the groundwater. Orthophosphate concentrations in MLC1 and MLC2 were lower than their assumed terrestrial end-members (Table 4.2). For these samples, phosphate may have absorbed onto particles along the groundwater flow path, or may have been utilized by plant roots and/or microbes in contact with the terrestrial waters closer to the harbor.

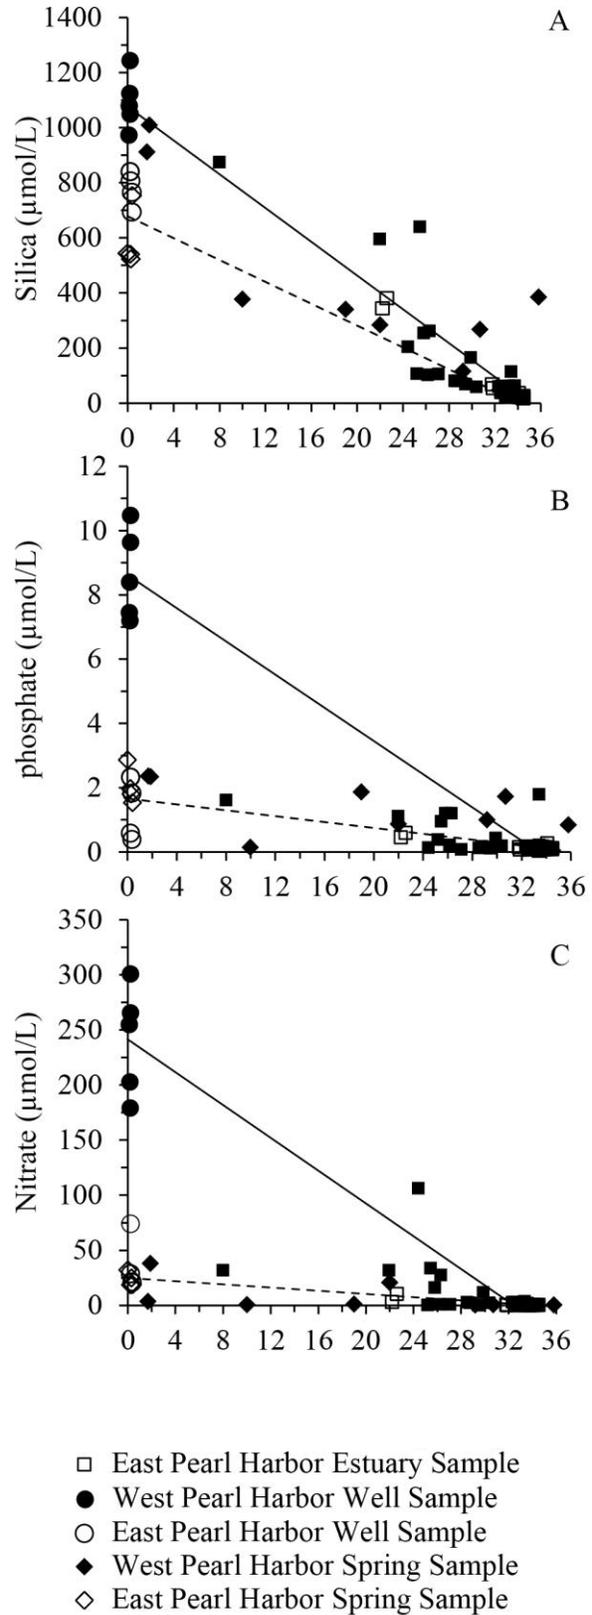

Nutrient concentrations in wells from the west side of the Pearl Harbor were similar in nitrate and varied from 179.1 to 300.7 $\mu\text{mol/L}$. Phosphate concentrations from these wells varied from 7.2 to 10.5 $\mu\text{mol/L}$. Well water from locations on the east side of the harbor was similar in nitrate, which varied from 20.7 to 73.9 $\mu\text{mol/L}$. Phosphate concentrations in these wells varied from 0.4 to 2.3 $\mu\text{mol/L}$.

Wells from the eastern side of Pearl Harbor were more comparable in dissolved nitrate, phosphate, and silica concentrations to the water supply wells located on the eastern side of Oahu (Figure 4.4) than to wells on the western side of Pearl Harbor (Table 4.2). These generalized patterns agreed with findings by Hunt (2004). The similarity between the eastern-most wells sampled on the island and wells on the eastern side of Pearl Harbor likely resulted because aquifers from these two areas are in communication with each other (Mink, 1980). Alternatively, or perhaps additionally, wells on the eastern side of Pearl Harbor did not receive the heavy agricultural irrigation and fertilizer applications that the west side of the harbor experienced. Similarly, the eastern side of Oahu experienced little agricultural land-use practices. Land-use patterns may have therefore imparted spatial heterogeneity in nutrient distributions reaching the harbor.

Spring and pore-water samples had variable dissolved inorganic nutrient concentrations, but all pore-water samples had higher salinities than the springs (Table 4.1). The higher salinities in the pore-water samples suggest that these samples interacted with more saline water in the subterranean estuary. Chemical reactions within the subterranean estuary likely modified terrestrially-derived groundwater entering the estuary (Burnett et al., 2003). The pore-water (WLC1, EC1, and EC2) and slow-flowing springs (WLC2, MLC3, and MLC4) had lower nitrate concentrations, higher nitrite and ammonium concentrations, and generally lower orthophosphate concentrations than the terrestrial end-members. This evidence suggested that chemical reactions did occur within Pearl Harbor's subterranean estuaries. Furthermore, many of the fast-flowing springs (all Waiiau HECO springs, MLC1, and MLC2) had nutrient characteristics comparable to terrestrial end-members, suggesting that limited chemical reactions occurred in the spring samples prior to discharge (Table 4.2)

Figure 4.5: Dissolved inorganic nutrients: A) silica, B) orthophosphate, and C) nitrate concentrations versus salinity for the west side of Pearl Harbor (closed symbols) and the east side of Pearl Harbor (open symbols). Solid lines represent theoretical mixing for the west side of Pearl Harbor and dashed lines represent theoretical mixing for the east side of Pearl Harbor. The water end-members used in the theoretical mixing are seawater, terrestrial water from west Pearl Harbor, and terrestrial water from east Pearl Harbor as described in Table 4.3.

Dissolved silica, orthophosphate, and nitrate are plotted relative to salinity in Figures 4.5A-C. Theoretical mixing lines, representative of conservative mixing, were drawn between the groundwater end-members from Pearl Harbor's west side and offshore seawater as well as for Pearl Harbor's east side and offshore seawater (Table 4.3). DSi concentrations were negatively correlated with salinity in groundwater, springs, pore-water, and estuary samples of surface-water (Figure 4.5A). The strength of this correlation suggested that DSi was predominantly controlled

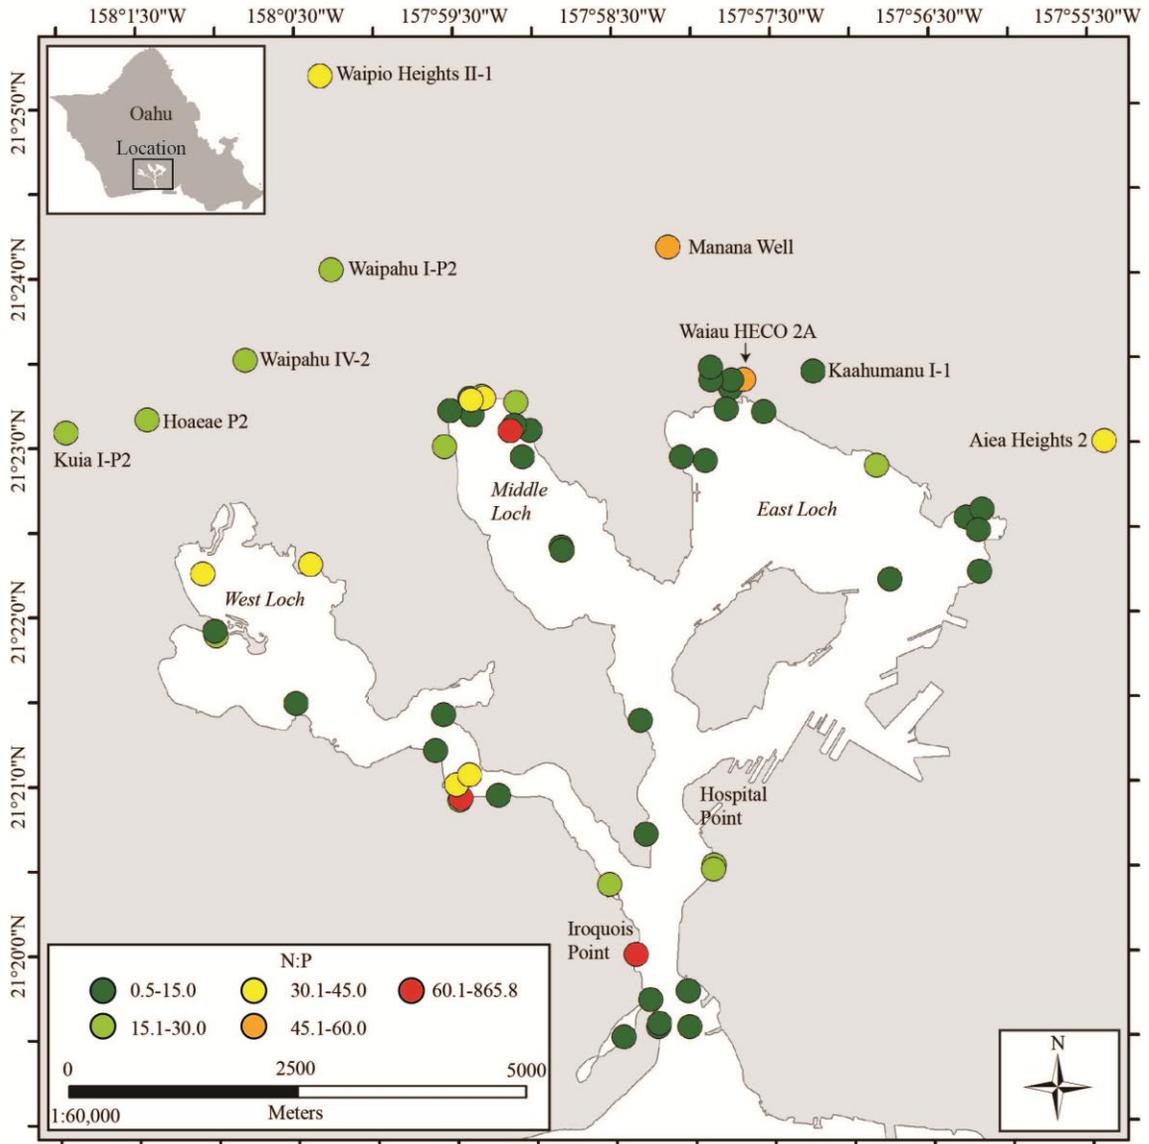

Figure 4.6: Dissolved inorganic nitrogen (nitrate+nitrite+ammonium) to orthophosphate ratios (displayed on a non-linear scale). Labeled locations represent water supply wells

by dilution once it reached Pearl Harbor's subterranean estuaries and estuary waters. Orthophosphate and nitrate samples deviated from the theoretical conservative mixing lines for both sides of the harbor. The deviation of dissolved nitrate and orthophosphate from their respective theoretical mixing lines (Figures 4.5B-C) suggested that these bioavailable nutrients were influenced by biological uptake and/or nutrient cycling on land and in Pearl Harbor's estuary.

Nitrogen to Phosphorus Ratios

N:P ratios for the harbor's surface waters averaged 16.0 ± 20.4 , 1SD, $n=43$, similar to the Redfield stoichiometric ratio for phytoplankton nutrients of N:P = 16:1 (Redfield, 1934). East Loch exhibited the lowest N:P ratios in the harbor (Figure 4.6). The average N:P for macroalgae is believed to be near 40:1 (Larned, 1998). The harbor may have been nitrogen-limited with respect to macroalgal nitrogen and phosphorus requirements, but did have nitrogen and phosphorus in adequate proportions for phytoplankton growth.

Dissolved Nitrate Stable Isotopes

Nitrogen and oxygen isotopic analyses of dissolved nitrate (Figure 4.7) were conducted on samples that had greater than $1.2 \mu\text{mol/L}$ of nitrate (minimum concentration required for analysis). All open water estuary samples (i.e. samples collected away from the shoreline) with the exception of WL1-5-1, WL1-6-1, and WLT1 had nitrate concentrations below the minimum requirement for analysis. The three exceptions likely represented recently discharged groundwater because they were located in proximity to cold temperatures on SST maps and areas of high ^{222}Rn activity (Chapter 3). There was adequate dissolved nitrate for analysis in most spring samples as well as several near-shoreline samples, which presumably contained a recently discharged groundwater component.

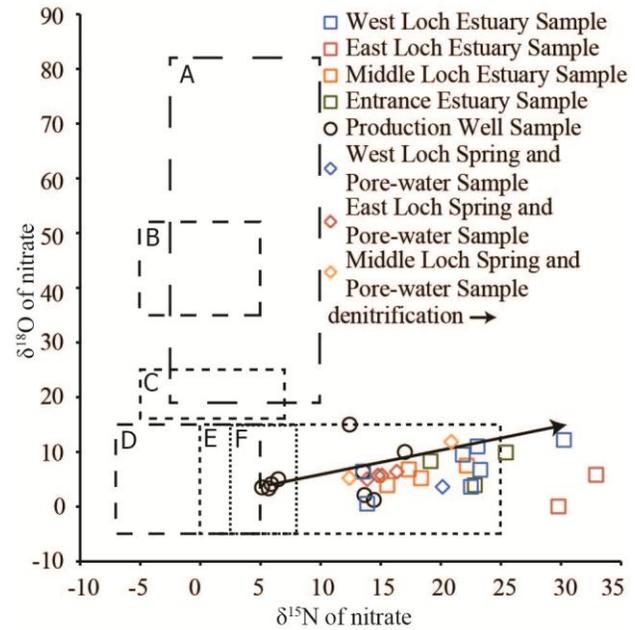

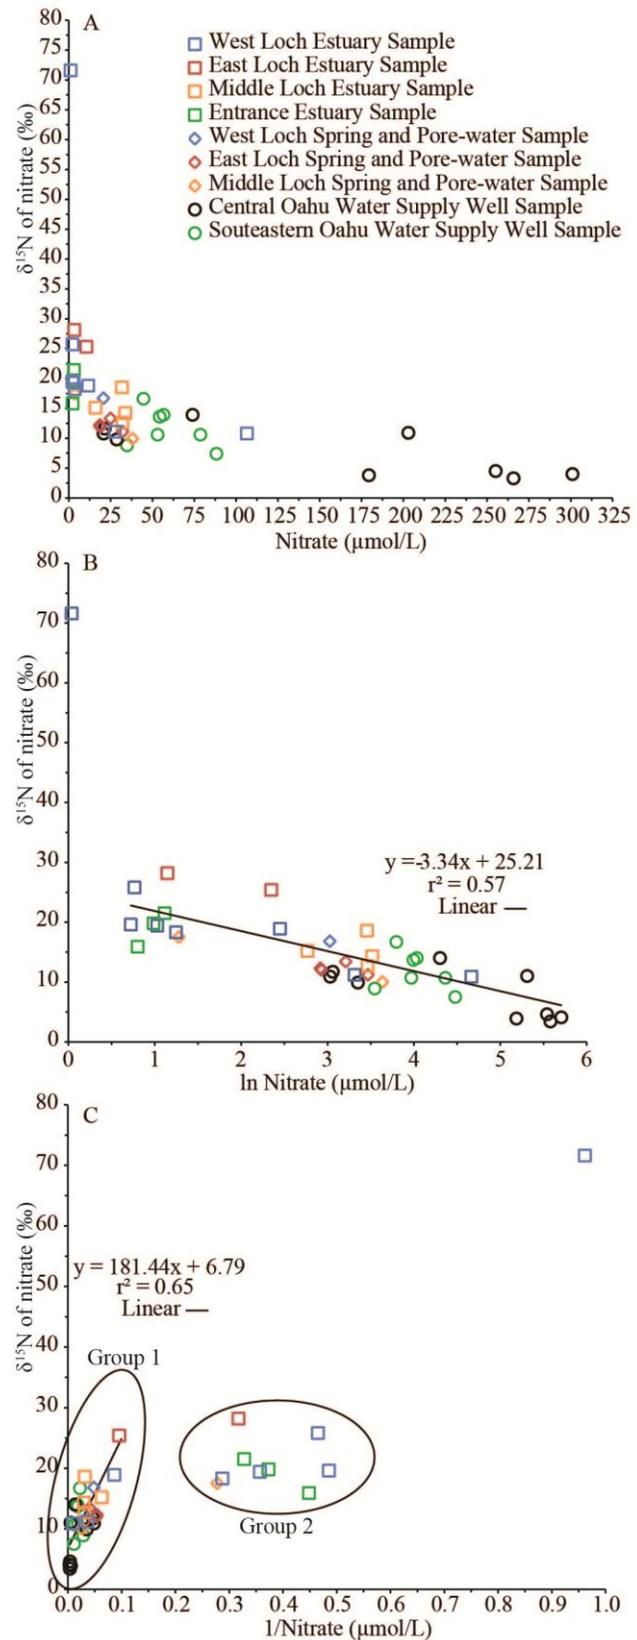

Figure 4.7: Cross-plot of $\delta^{18}\text{O}(\text{nitrate})$ versus $\delta^{15}\text{N}(\text{nitrate})$ delineated by sample type. All box designation letters are in the upper left hand corners of each box. A) nitrate in precipitation and atmospheric deposition, B) desert nitrate, C) fertilizer nitrate, D) nitrification of ammonium in fertilizer and rain, E) manure and septic waste, and F) soil nitrogen sources. Box designations are after Kendall (1998) and Mayer (2005). Sample WLT-2 with $\delta^{15}\text{N} = +71.6\text{‰}$ and $\delta^{18}\text{O} = +7.1\text{‰}$ is omitted for clarity.

Figure 4.8: A) $\delta^{15}\text{N}(\text{nitrate})$ versus nitrate concentration, B) $\delta^{15}\text{N}(\text{nitrate})$ versus the natural log of nitrate concentration, and C) $\delta^{15}\text{N}(\text{nitrate})$ versus $1/[\text{NO}_3^-]$.

Water supply wells, including Kunia 1 P-2, Hoaeae P-2, Waipahu IV-2, and Waipio Heights II-1 had similar nitrogen and oxygen isotopic compositions (Figure 4.7) that plotted in the overlapping region of nitrate derived from mineralization of soil organic matter (Figure 4.7, box F) and nitrate derived from ammonium fertilizer and rain (Figure 4.7, box D). These samples also plotted in an overlapping region that encompassed nitrate from manure and septic waste (Figure 4.7, box E). Most of the remaining samples plotted in box F (Figure 4.7), which represents samples with nitrate from septic waste. The samples showed signs of fractionation and mixing processes (Figures 4.8A-C) and may have simply plotted in box F due to these overprinting processes (see discussion below).

The hyperbolic pattern of

increasing $\delta^{15}\text{N}(\text{nitrate})$ with decreasing nitrate concentration in Figure 4.8A indicates loss of nitrate by an isotopically fractionating process. This loss of nitrate likely occurred as the water flowed from water supply wells to the coastal springs as demonstrated by lower nitrate concentrations and higher $\delta^{15}\text{N}(\text{nitrate})$ values in spring waters than in water supply wells. This process continued as water flowed through the subterranean estuary as evidenced by the lower nitrate concentration and higher $\delta^{15}\text{N}(\text{nitrate})$ values in pore-waters than in either spring or water supply well samples. Denitrification and photosynthetic uptake are two possibilities for such a fractionating process. During denitrification, ^{14}N reacts more rapidly than ^{15}N , causing enrichment of ^{15}N in the remaining nitrate (Kendall, 1998). Typical enrichment factors for denitrification range from -5 to -30‰ (Mariotti et al., 1988; Sigman and Casciotti, 2001). During photosynthetic uptake, phytoplankton preferentially consume ^{14}N relative to ^{15}N (Sigman and Casciotti, 2001). A typical enrichment factor for uptake is -5‰ (Sigman and Casciotti, 2001). All enrichment factors were defined by the Rayleigh model after Kendall (1998):

$$\delta_R \approx \delta_{R_0} + \varepsilon \ln \frac{C}{C_0} \quad (4.1)$$

where δ_R is the nitrogen or oxygen isotopic composition of the reactant, δ_{R_0} is the initial nitrogen or oxygen isotopic composition, ε is the enrichment factor, C is the measured concentration, and C_0 is the initial concentration.

The roughly linear correlation in Figure 4.8B ($r^2=0.57$) in the cross-plot of $\delta^{15}\text{N}(\text{nitrate})$ versus natural log of $[\text{NO}_3^-]$ is indicative of the presence of a fractionating process for at least some of the samples. The -3.3 slope of the regression in Figure 4.8B represents an average nitrogen enrichment factor derived from nitrate ($^{15}\varepsilon$) of -3.3‰ for the field area. Average $^{15}\varepsilon$ calculated by loch were -3.4‰ for West Loch ($n=13$, $r^2=0.87$), -3.4‰ for Middle Loch ($n=11$, $r^2=0.74$), and -6.1‰ for East Loch ($n=8$, $r^2=0.60$). In contrast, the average oxygen enrichment factor derived from nitrate ($^{18}\varepsilon$) was -1.0‰ for the harbor ($r^2=0.21$). Average $^{18}\varepsilon$ calculated by loch were -1.1‰ for West Loch ($n=13$, $r^2=0.44$), -1.5‰ for Middle Loch ($n=11$, $r^2=0.65$), and +1.4‰ for East Loch ($n=8$, $r^2=0.06$). Fewer samples were available for East Loch to calculate end-member characteristics, thus the enrichment factors for East Loch likely do not reflect

representative processes or end-members for the loch and will not be considered in the discussion below.

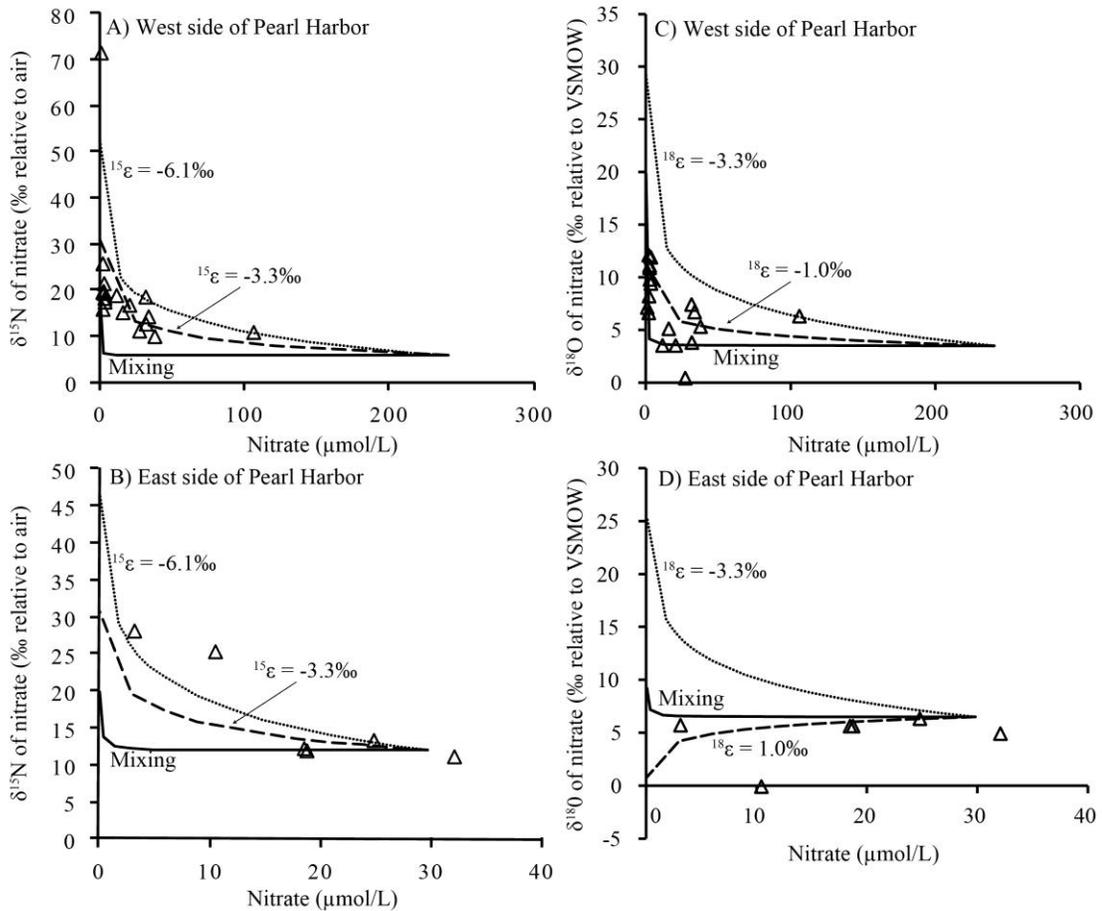

$^{15}\epsilon$ for the harbor as a whole, as well as for West and Middle Lochs were not consistent with published enrichment factors for denitrification or uptake. Green et al. (1998) published a similar enrichment factor of -3.0‰ from Jersey Island. Green et al. (1998) suggested that their enrichment factor could have resulted from fast denitrification at high temperatures, or could have reflected mixing between low- and high-nitrate groundwaters with similar isotopic compositions.

Assimilation by phytoplankton and by alga as well as denitrification has been shown to have $^{15}\epsilon$: $^{18}\epsilon$ ratios of nearly 1:1 for oceanic systems (Sigman et al., 2003; Granger et al., 2004). Lehmann et al. (2003) found $^{15}\epsilon$: $^{18}\epsilon$ of 1.4 to 2.0 for denitrification in freshwater systems. The average $^{15}\epsilon$: $^{18}\epsilon$ ratio is 3.3 for Pearl Harbor, with 3.1 for West Loch and 2.3 for Middle Loch. The $^{15}\epsilon$: $^{18}\epsilon$ ratios suggest that assimilation and denitrification are not major processes controlling nitrogen cycling in the harbor.

Denitrification does occur in aquifers in the Hawaiian Islands (Hunt and Rosa, 2009; Fackrell, unpublished.). Fackrell (unpublished) calculated enrichment factors of -18.9‰ for the Lahaina, Maui area. However, it is our experience that most aquifers in the Hawaiian Islands have predominantly oxic conditions and are therefore not conducive to denitrification. The high concentrations of nitrate and low concentrations of nitrite and ammonium in the water supply wells and fast-flowing springs also support this conclusion. The more stagnant spring sources as well as the pore-water samples, on the other hand, had lower nitrate concentrations than their freshwater end-members and larger nitrite and ammonium concentrations than their freshwater end-members. $^{15}\epsilon$ for these samples was still -3.2‰ despite the lower nitrate and higher nitrite and ammonium concentration in these samples. The enrichment factor for oxygen ($^{18}\epsilon$) for these samples was -1.5‰. $^{15}\epsilon$: $^{18}\epsilon$ for these samples was 2.1, which is larger than previously determined enrichment factor ratios for either denitrification or uptake. We therefore hypothesize that the groundwater end-members may not be representative of the water flowing into the more stagnant pools.

In addition to a fractionating process, mixing also occurred in the field area, as indicated by the group 1 samples on the left side of Figure 4.8C. These samples follow a

linear trend ($r^2=0.65$, $n=34$) in the plot of $\delta^{15}\text{N}(\text{nitrate})$ versus $1/[\text{NO}_3^-]$. Group 2 in Figure 4.8C is predominantly composed of samples from near the W4 pier in West Loch and samples collected near the shoreline along the main channel entrance to the harbor (with the exception of MLC3 and one shoreline surface water sample collected on the east side of East Loch, EL5-1-1). These samples do not show a mixing relationship.

We used the end-members described in Table 4.3 to generate cross-plots of the samples with progressive mixing curves and Rayleigh fractionation curves (Figures 4.9A-

Figure 4.9: $\delta^{15}\text{N}$ of nitrate versus nitrate concentration for A) the west side of Pearl Harbor and B) the east side of Pearl Harbor. $\delta^{18}\text{O}$ of nitrate versus nitrate concentration for C) the west side of Pearl Harbor and D) the east side of Pearl Harbor. Table 4.3 contains the end-member descriptions. Solid lines represent mixing between the two end-members. The dotted and dashed lines represent progressive isotopic composition resulting from Rayleigh fractionation for various isotope effects observed in Pearl Harbor (see discussion).

D). Progressive mixing curves were calculated after Mariotti et al. (1988):

$$\delta_m = \frac{Q_a(\delta_a - \delta_b)}{Q_m} + \delta_b \quad (4.2)$$

eq. 4.2 describes mixing between two water of types “a” and “b,” where δ_m is the isotopic composition of the mixture, Q_a is the volume of water “a” multiplied by the nitrate concentration of water “a”, δ_a is the isotopic composition of water “a”, δ_b is the isotopic composition of water “b”, and Q_m is the volume of the water mixture multiplied by the nitrate concentration of the water mixture.

Rayleigh fractionation curves in Figures 4.9A-D were calculated from eq. 4.1. Most of the samples plotted between the mixing curve and the average Rayleigh fractionation curve with a $^{15}\epsilon$ value of -3.3‰ (Figures 4.9A-B). In contrast, plots of $^{18}\epsilon$ and mixing curves show that most of the samples from the west side of Pearl Harbor plotted on the mixing curve in Figure 4.9C. Fewer samples plotted between the mixing curve and the average Rayleigh fractionation curve with a $^{18}\epsilon$ value of -1.0‰ (Figure 4.9C). For the east side of harbor, most samples plotted between the mixing curve and the average Rayleigh fractionation curve with a $^{18}\epsilon$ value of 1.0‰. The simplest explanation of the above relationships is mixing combined with end-members that may not be indicative of all sources of water and nutrients to the harbor.

Further end-member testing and likely use of multiple tracers is required to specifically identify nitrate sources and nutrient transformations within Pearl Harbor. The isotopic variation of ~25‰ in nitrogen and ~15‰ in oxygen suggests that, with better end-member constraints, it should be possible to determine the ultimate source(s) of nitrogen based on isotopic analyses of nitrate in groundwater and isotopic analyses of $\delta^{15}\text{N}$ of nearshore macroalgae.

Nutrient Fluxes to Pearl Harbor

To calculate nutrient fluxes to Pearl Harbor, an estimate of the nutrient concentrations for the discharging groundwater end-member must be established and then multiplied by a groundwater discharge rate from the coastline. Although the calculation is fairly simple in principle, proper designation of the groundwater end-member is crucial for meaningful nutrient budgets to result. Slomp and Van Cappellen (2004) and Charette and Sholkovitz (2006) have shown that chemical transformations in the subterranean

estuary can impact the dissolved species concentrations that are discharged to a water body. Thus, it may not always be appropriate to use nutrient concentrations measured in the fresh groundwater end-member to estimate nutrient fluxes to a coastal zone (Santos et al., 2008).

Assigning nutrient concentrations in groundwater is complicated in Pearl Harbor because the harbor exhibits at least two distinct groundwater discharge processes. Pearl Harbor's springs are thought to discharge from near the top of the groundwater transition zone (Visher and Mink, 1964) and likely spend little time or even directly by-pass the subterranean estuary. Anthropogenic-sourced nutrients and other dissolved constituents discharging from spring sources may do so without heavily interacting with the subterranean estuary. On the other hand, Pearl Harbor's diffuse (non-point source) discharge should interact with the subterranean estuary, changing the water's chemical composition before discharging to Pearl Harbor (discussion above and Table 4.2). We collected multiple samples of spring water and established representative estimates for the average composition of the dissolved nutrients of the spring discharge. We also collected three pore-water samples, but cannot extrapolate the nutrient concentrations in those samples to the whole harbor with any certainty. We therefore, cannot characterize the dissolved nutrient concentrations of the diffuse component or any other discharge that interacts with the subterranean estuary and eventually discharges through the sediment/water interface.

Multiple groundwater end-members can be adopted (e.g. Santos et al., 2008) for a field area. The ideal scenario for Pearl Harbor would be to apply at least four groundwater end-members. These end-members would include terrestrial water from the west side of Pearl Harbor, subterranean estuary water from the west side of the harbor, terrestrial water from the east side of the harbor, and subterranean estuary water from the east side of Pearl Harbor. Since we cannot characterize the subterranean estuary end-members with certainty, we chose to use the terrestrial end-members from the west and east sides of Pearl Harbor (Table 4.3). We also applied these end-members based on the assumption that most of the groundwater flow to Pearl Harbor occurred through the springs (Chapter 3).

Our application of average groundwater end-members for use in nutrient flux calculations does not capture local factors such as potential increased anthropogenic inputs near golf courses or increased inputs near communities with cesspools, for example. Several streams contributed water to the harbor; however, most of these streams were groundwater-fed. We made no attempt to differentiate nutrient signatures from recently discharged groundwater and stream flow. Nutrient uptake by algae and plants (e.g. mangroves) in and near each stream was also not considered. The local variations due to increased nutrient loads would cause the nutrient flux estimates to the harbor to be underestimates, while uptake by algae and other plants would result in overestimates of nitrate and orthophosphate nutrient loads to the harbor.

^{222}Rn is sensitive to groundwater discharged within the past ~20 days (^{222}Rn half life of 3.82 days X 5 decay cycles). We calculated groundwater fluxes to Pearl Harbor using a ^{222}Rn coastal box model developed by Dulaiova et al. (2005) and modified by Dulaiova et al. (2010). This model used ^{222}Rn activities measured from a survey of surface waters and is described in detail in Chapter 3. Briefly, ^{222}Rn activities, water temperature, water salinity, water depth, air wind speed, and latitude/longitude data were input into the model. All ^{222}Rn measurements were converted to total groundwater fluxes based on eq. 4.3 after Moore (1996).

$$Q_{SGD_{tot}} = \frac{A_{Rn_{cw}} * V}{\tau * A_{Rn_{gw}}} \quad (4.3)$$

where $Q_{SGD_{tot}}$ is total (fresh and saline) groundwater discharge in m^3/d . $A_{Rn_{cw}}$ and $A_{Rn_{gw}}$ are ^{222}Rn activities in coastal water and groundwater in dpm/m^3 , V is the volume of the coastal water box in m^3 represented by the ^{222}Rn measurement and τ is the flushing rate of the volume of water considered in the calculation. As described in Chapter 3, we utilized a tidal flushing rate (12 hours 15 minutes) and a variable (by location) flushing rate described by Buske and Evans (1974). The tidal flushing rate assumed that each coastal box in the model was flushed uniformly quickly. This flushing rate generated maximum estimates of groundwater fluxes for the all lochs and minimum estimates for the mouth of the harbor. The flushing rates proposed by Buske and Evans (1974) ranged from hours to days in the back of East and Middle Lochs, to 30 minutes near the mouth of the harbor. The groundwater fluxes from the variable flushing rate represented

minimum estimates in the back of East and Middle Lochs and maximum estimates near the mouth of the harbor. No variable flushing rate data were available for West Loch (Buske and Evans, 1974). Groundwater fluxes calculated by ^{222}Rn mass balance (Chapter 3) represented minimum estimates for several reasons. First, recently discharged groundwater to spring-fed streams had the potential for radon degassing, which would make degassed water transparent to the ^{222}Rn tracer. Second, runoff and drainage from each stream's watershed would have been naturally low in ^{222}Rn , and would not have been detected by the surveys. Finally, we were unable to survey the entire shoreline of the harbor (Chapter 3).

After groundwater fluxes were calculated, the fluxes were multiplied by the nutrient concentrations of the appropriate terrestrial end-member (Table 4.3). We incorporated a salinity balance into our nutrient budget to accommodate mixing of seawater and freshwater by using the theoretical mixing lines between each dissolved nutrient species and salinity shown in Figures 4.5A-C. DSi budgets will generate the most accurate flux estimates compared to dissolved nitrate and phosphate since the DSi data more closely fit the theoretical mixing line. Dissolved nutrient contributions from nitrate and phosphate were over-estimated in most cases. Estuary samples typically had dissolved nitrate and phosphate concentrations that plotted below the theoretical mixing line and represented non-conservative mixing (Figures 4.5B-C). In our model, atmospheric deposition of nutrients was ignored since it is minimal on the time-scale of our budget calculations (Vitousek, 2004). Nutrient inputs by precipitation were also ignored because no precipitation occurred during the surveys.

For the tidal flushing rate, DSi contribution from West Loch was 8,600 mol/d, Middle Loch was 11,700 mol/d, East Loch was 10,300 mol/d, and the harbor mouth was 1,900 mol/d, totaling 32,500 mol/d. For nitrate, West Loch contributed 1,800 mol/d, Middle Loch contributed 2,500 mol/d, East Loch contributed 400 mol/d and the mouth of the harbor contributed 100 mol/d, totaling 4,800 mol/d. Phosphate loads to the harbor included 70 mol/d from West Loch, 90 mol/d from Middle Loch, 30 mol/d from East Loch, and <10 mol/d from the mouth of the harbor, totaling 200 mol/d. In comparison, for the variable flushing rates proposed by Buske and Evans (1974), DSi contribution from Middle Loch was 5,000 mol/d, East Loch was 7,100 mol/d, and the mouth of the

harbor was 4,700 mol/d, totaling 16,800 mol/d plus unknown contributions from West Loch. For nitrate, Middle Loch contributed 1,000 mol/d, East Loch contributed 300 mol/d and the mouth of the harbor contributed 700 mol/d, totaling 2,000 mol/d plus unknown contributions from West Loch. Phosphate loads to the harbor included 30 mol/d from Middle Loch, 20 mol/d from East Loch, and 40 mol/d from the mouth of the harbor, totaling 90 mol/d plus unknown contributions from West Loch.

On a per-m length of shoreline basis, West Loch contributed, on average, 332,300 $\mu\text{mol/d/m}$ of DSi, Middle Loch contributed 1,539,341 $\mu\text{mol/d/m}$, East Loch contributed 831,000 $\mu\text{mol/d/m}$ and the mouth of the harbor contributed 82,500 $\mu\text{mol/d/m}$ of DSi (Figures 4.10A-C) based on tidal flushing rates. For dissolved nitrate, on average, West Loch contributed 69,700 $\mu\text{mol/d/m}$, Middle Loch contributed 334,800 $\mu\text{mol/d/m}$, East Loch contributed 646,400 $\mu\text{mol/d/m}$ and the entrance contributed 12,900 $\mu\text{mol/d/m}$ (Figures 4.11A-C) for tidal flushing rates. For orthophosphate, on average, West Loch contributed 2,700 $\mu\text{mol/d/m}$, Middle Loch contributed 12,200 $\mu\text{mol/d/m}$, East Loch contributed 5,100 $\mu\text{mol/d/m}$ and the mouth of the harbor contributed 600 $\mu\text{mol/d/m}$ (Figures 4.12A-C). In comparison, the variable flushing rates proposed by Buske and Evans (1974) yielded, on average, 694,000 $\mu\text{mol/d/m}$ for Middle Loch, 572,900 $\mu\text{mol/d/m}$ for East Loch, and 354,200 $\mu\text{mol/d/m}$ of DSi for the mouth of the harbor. For dissolved nitrate, 151,300 $\mu\text{mol/d/m}$ came from Middle Loch, 23,700 $\mu\text{mol/d/m}$ came from East Loch and 55,300 $\mu\text{mol/d/m}$ came from the mouth of the harbor, on average. For orthophosphate, Middle Loch contributed 4,000 $\mu\text{mol/d/m}$, East Loch contributed 1,800 $\mu\text{mol/d/}$ and the mouth of the harbor contributed 3,100 $\mu\text{mol/d/m}$, on average. Compared to SGD-derived nutrient inputs to other Hawaiian coastlines, Pearl Harbor contributed similar silica, nitrate, and phosphate loads on a per-m length of shoreline basis (see Johnson 2008 for a compilation).

Conclusions

We have demonstrated that nutrient characteristics of fresh groundwater end-members are heterogeneous, but may be broadly separated into two distinct groups, one for the west side of Pearl Harbor and one for the east side of Pearl Harbor. The

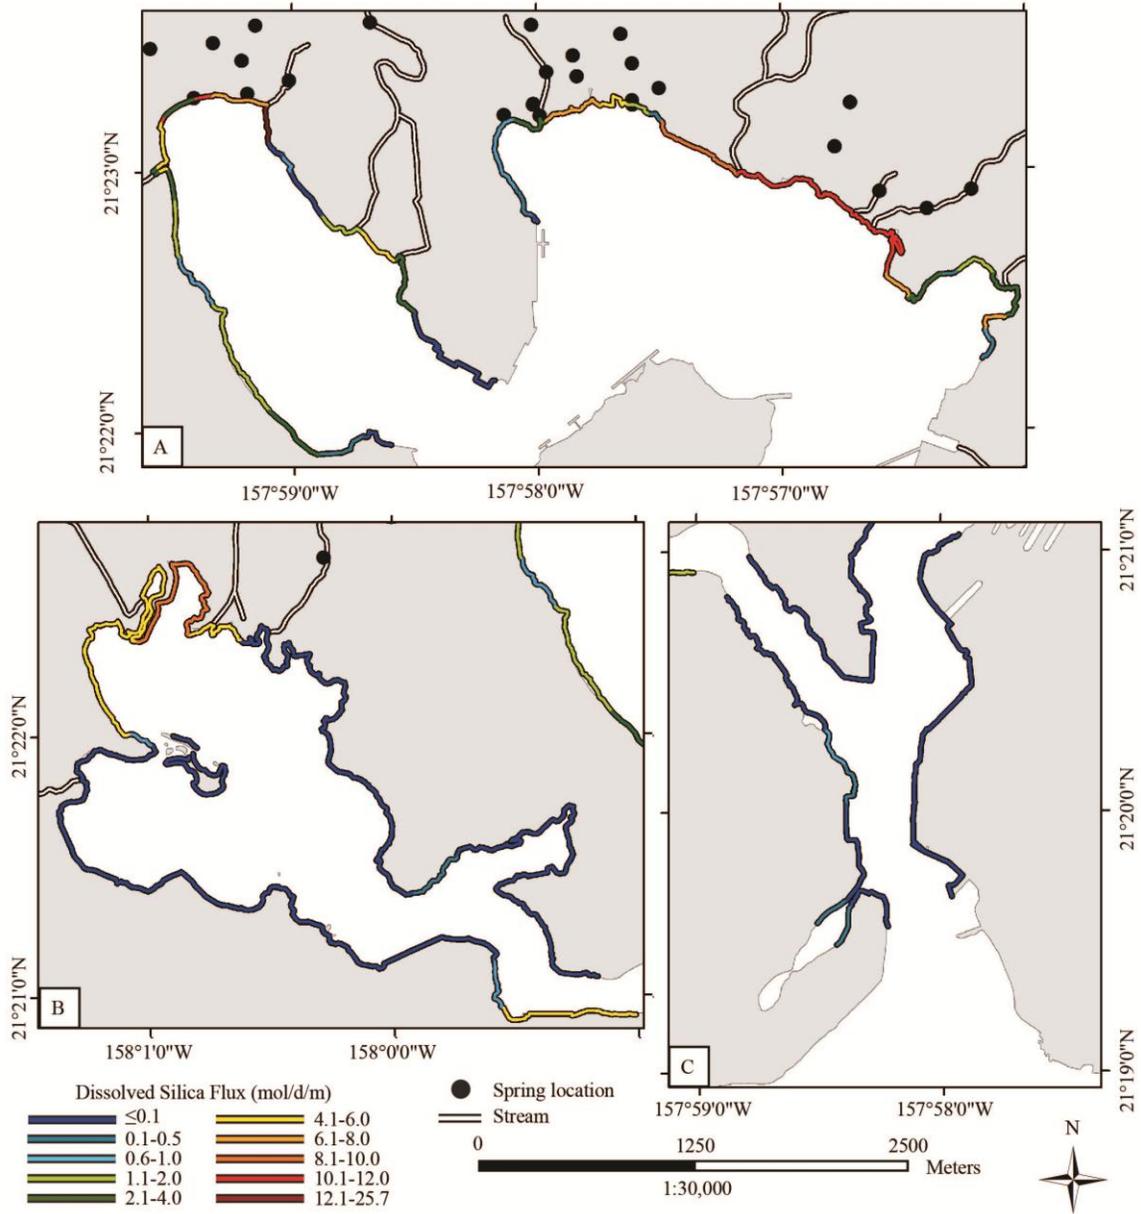

Figure 4.10: DSi fluxes from recently discharged groundwater A) Middle Loch survey (left) collected on 8 January 2010 and East Loch survey (right) collected on 4 January 2010, B) West Loch survey collected on 2 January 2010, and C) mouth of Pearl Harbor survey collected on 10 January 2010. Nutrient concentrations are reported on a non-linear scale to better differentiate lower fluxes from higher fluxes. End-members are described in Table 4.3. Subaerial spring locations are after Stearns and Vaksvik (1935).

Nutrient concentrations are reported on a non-linear scale to better differentiate lower fluxes from higher fluxes. End-members are described in Table 4.3. Subaerial spring locations are after Stearns and Vaksvik (1935).

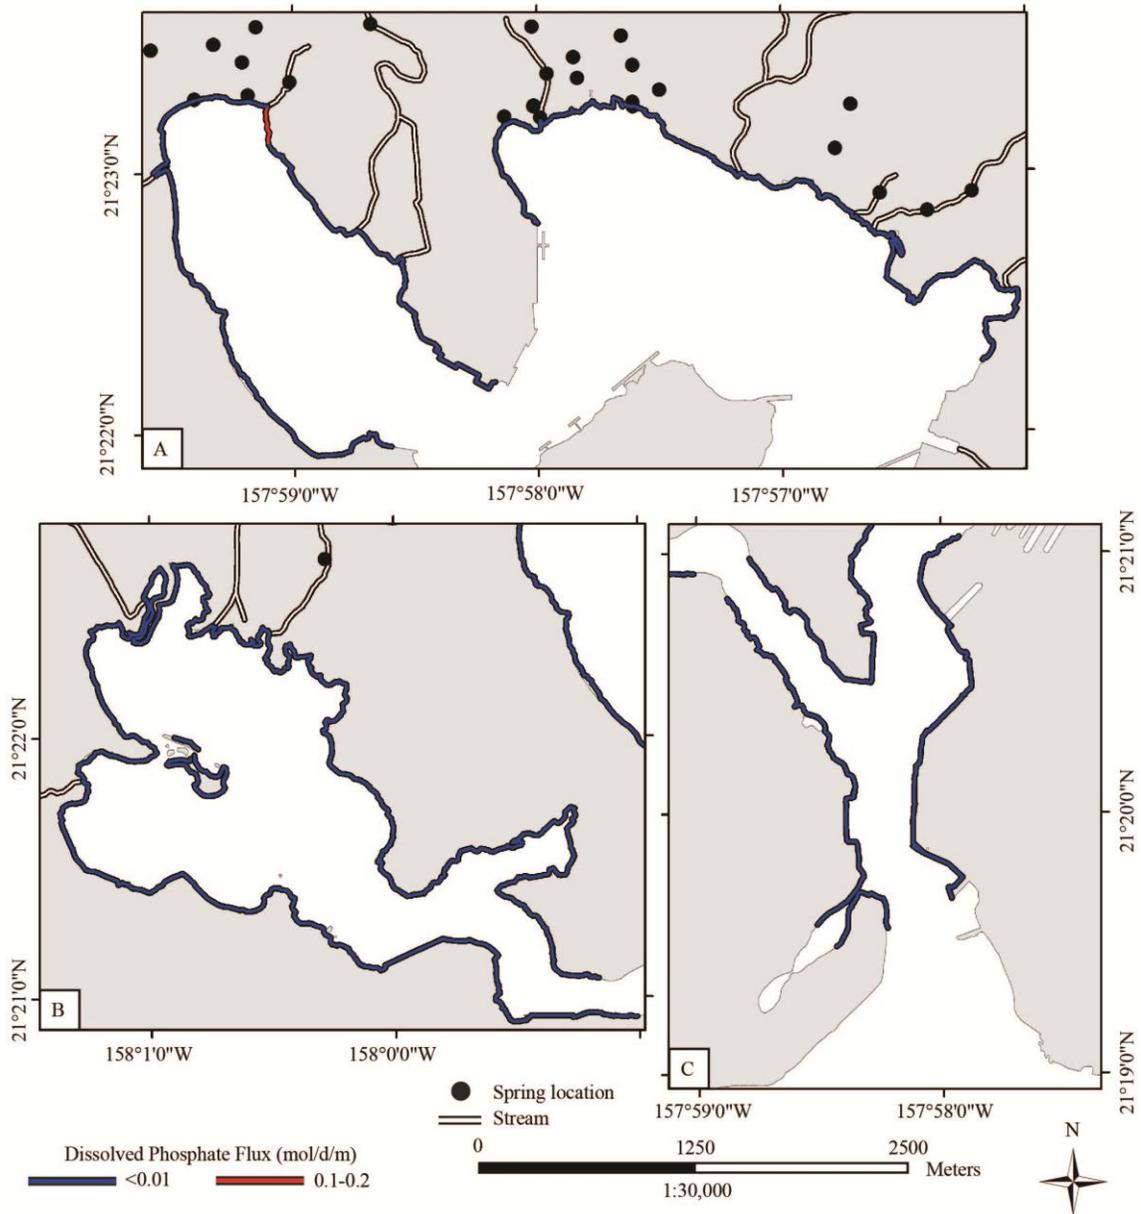

Figure 4.12: Dissolved PO_4^{3-} fluxes from recently discharged groundwater A) Middle Loch survey (left) collected on 8 January 2010 and East Loch survey (right) collected on 4 January 2010, B) West Loch survey collected on 2 January 2010, and C) mouth of Pearl Harbor survey collected on 10 January 2010. Nutrient concentrations are reported on a non-linear scale to better differentiate lower fluxes from higher fluxes. End-members are described in Table 4.3. Subaerial spring locations are after Stearns and Vaksvik (1935).

heterogeneity in the two groups likely stems from large-scale agricultural processes on the west side of the harbor and the more urbanized land-use on the east side of Pearl

Harbor. Land-use patterns have likely imparted spatial heterogeneity in nutrient distributions reaching harbor waters.

The nitrogen isotopic data are consistent with four water supply wells that have nitrate sourced either from soils or from nitrate in fertilizer and rain. Mixing between water sources is likely and better characterization of the various end-members is necessary for a more comprehensive assessment of the processes occurring in the harbor. Dissolved nutrient loads of silica, nitrate, and orthophosphate to the harbor vary by loch. Minimum estimates for nutrient contributions to the harbor by recently discharged groundwater include between 2,000 and 4,800 mol/d of dissolved nitrate, between 90 and 200 mol/d of orthophosphate, and between 16,800 and 32,500 mol/d of dissolved silica. The estimates of nutrient loads compare to other Hawaiian shorelines.

CHAPTER 5. CHLOROFLUOROCARBON APPARENT AGES OF GROUNDWATERS IN WESTERN HAWAII

Introduction

Geohydrological budgets (Shade, 1995a, 1995b; Shade and Nichols, 1996; Shade, 1997) suggest that nearly all groundwater recharge to Hawaiian aquifers eventually discharges to the sea. Investigations utilizing aerial thermal infrared surveying and ^{222}Rn mass balance models have definitively established that large quantities of groundwater discharge into Kona (western), Hawaii coastal zones as submarine groundwater discharge (SGD; Peterson et al., 2007; Johnson et al., 2008; Street et al., 2008; Peterson et al., 2009; Knee et al., 2010; Holleman, 2011). On the Kona Coast, SGD flux always exceeds river inputs since the area contains no perennial streams (Johnson et al., 2008).

Despite prolific groundwater discharge, little is known about aquifer geometries, aquifer recharge areas, groundwater residence times, and groundwater flow paths. This knowledge is beneficial for groundwater resource management since groundwater is utilized for almost all of the area's freshwater needs. This aquifer knowledge can also help assess changes of the groundwater resources through time. Modification of land-use practices and climatological patterns, for example, can affect dissolved nutrient concentrations and the quantity of groundwater in the aquifer. These impacts will influence SGD and, therefore, coastal ecosystems. Assessing SGD holistically, from the point of recharge to the impacts of its discharge on coastal ecosystems, is an important next step for areas with prolific SGD like the Kona Coast.

We conducted this study to test the hypothesis that chlorofluorocarbon (CFC) apparent age dating could be utilized in the relatively pristine Kona Coast to determine aquifer residence times. We also hypothesized that groundwater's oxygen and hydrogen isotopic composition could help locate potential recharge areas. If successful, our goal was to apply the residence time information to better understand the area's SGD resources.

We present an integrated approach for using oxygen and hydrogen isotopic compositions of groundwater, $\delta^{18}\text{O}$ /altitude gradients, and lapse rates to determine recharge elevations and water temperatures for groundwater samples. We demonstrate that apparent groundwater ages from chlorofluorocarbons (CFCs) can be established for

the relatively pristine aquifers of the Kona Coast. We also show that CFCs may be useful for distinguishing between groundwater from different aquifer systems.

Chlorofluorocarbons

Anthropogenic activities related to industrial, commercial, and household applications prompted manufacture and release of CFCs into the atmosphere, beginning in the 1930s (CFC-11 and CFC-12) and 1940s (CFC-113; Plummer and Busenberg, 2000; Happell et al., 2006; Plummer and Busenberg, 2006a). CFC use was terminated in the U.S. in 1995 (Cook et al., 2003) to curtail their deleterious effects on Earth's ozone layer. Each CFC compound had unique atmospheric concentrations through time because of their different production and release schedules. Since CFCs are stable and water soluble, they have been imbibed into Earth's hydrologic cycle through precipitation, infiltration, and groundwater recharge. CFC incorporation into the hydrologic cycle has closely followed their

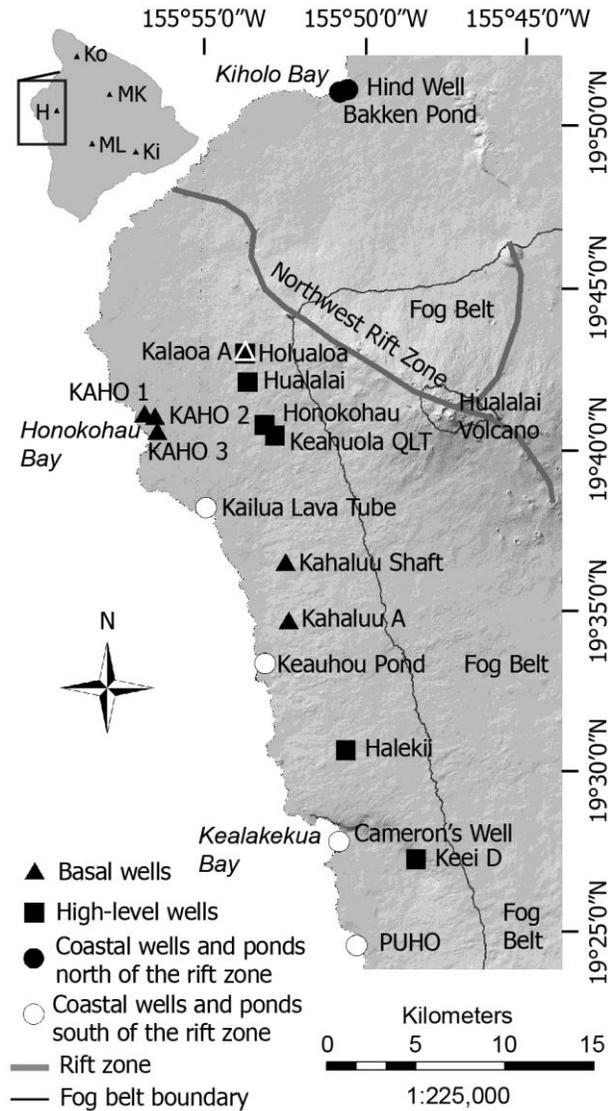

Figure 5.1: Sample locations delineated by basal wells, high-level wells, coastal wells and ponds north of Hualalai Volcano's northwest rift zone, and coastal wells and ponds south of the rift zone. Areas east of the lower fog belt boundary (975 m) lie within the fog belt zone. Hualalai's summit is above the upper fog belt boundary at 2,255 m. Kalaoa A is a basal well located within undistinguishable proximity, at the scale of this figure, to Holualoa and is outlined in white. Locations of the five mountains of Hawaii Island are shown in the inset map: Ko=Kohala, MK=Mauna Kea, H=Hualalai, ML=Mauna Loa, and Ki=Kilauea.

production, making CFCs excellent tracers and age determination tools for water younger than ~60 years (Plummer and Busenberg, 2000).

Materials and Methods

Subsurface Geology and Groundwater Occurrence of Western Hawaii

Hawaii Island is composed of numerous lava flows with variable thicknesses and composition. The permeability of the rocks is heterogeneous, but is high overall (Stearns and MacDonald, 1946). Aa lava clinker zones, voids between lava flow contacts, cooling joints normal to flow surfaces, and lava tubes contribute to the aquifer's high permeability (Stearns and MacDonald, 1946). Fractures and the permeability features mentioned above facilitate rapid groundwater transport through the aquifer (Oki et al., 1999). Peterson et al. (2007), Johnson et al. (2008), Street et al. (2008), and Peterson et al. (2009) have found that focused SGD points in numerous areas of this coastal zone result from these geological controls.

All Hawaiian volcanoes contain low permeability and low hydraulic conductivity dike complexes, which are typically associated with rift zones (Takasaki and Mink, 1985). The northwest rift zone of Hualalai Volcano bisects the study area (Figure 5.1). The rift zone consists of a 1.9 to 4.0 km wide and 21.1 km long subaerial portion as well as a submarine portion (not shown; Oki, 1999). Oki (1999) considers the rift zone a groundwater divide and no-flow boundary.

Dikes are believed to be most abundant within central rift zones, and are hydrologically important because they may extend vertically and laterally for thousands of meters (Oki et al., 1999). Dikes complexes compartmentalize the more permeable intruded rocks, creating isolated and slightly leaky groundwater reservoirs (Oki et al., 1999). Aquifers resulting from dike complexes are locally referred to as high-level aquifers. These aquifers typically have water levels >12 m above sea-level (Oki et al., 1999).

Fresh groundwater near dike-free coastal areas exists in a freshwater lens that floats on denser saltwater roughly according to Ghyben-Herzberg principles. Water in this aquifer is locally referred to as basal water, and generally has water levels <3 m above sea-level (Oki et al., 1999). It is this basal water that should discharge to coastal areas as SGD.

Climate of Western Hawaii

Coastal areas of Western Hawaii experience little seasonal temperature fluctuation with a mean annual temperature of 23.7°C. High temperatures vary between 26 and 29°C and low temperatures approach 21°C (Nullet and Sanderson, 1993). The tallest topographic feature in the study area is Hualalai volcano at 2,521 m. Hualalai's summit has a mean annual air temperature of 10.6°C.

On the Kona Coast, east-flowing sea breezes converge daily with west-flowing northeast trade winds. The trade winds pass between Mauna Kea and Mauna Loa (Figure 5.1 inset) as well as atop Mauna Loa's upper slopes. The wind pattern results in afternoon rainfall over the ocean that drifts toward the shore at night (Schroeder, 1993). Summer months experience a high frequency of late afternoon and early evening showers, making the Kona Coast the only region in the Hawaiian Islands where summer rainfall exceeds winter rainfall (Schroeder, 1993). Despite this unique rainfall pattern, the area resides in the rain-shadow of several large mountains and is classified as having a rain-shadow microclimate (Scholl et al., 2002).

A fog belt exists in the field area (Figure 5.1) predominantly between 975 and 2,255 m altitude (County of Hawai'i, 2003), but never extends lower than 760 m (Juvik and Ekern, 1978). When trade winds are forced to ascend mountainous areas, persistent mountain-hugging clouds form (Giambelluca and Sanderson, 1993). Often, formation of these clouds is limited by the base of a trade wind inversion, which commonly occurs between 1,500 and 3,000 m (Giambelluca and Schroeder, 1998). The inversion layer prevents large raindrops from forming and produces high ratios of fog to rain near the base of the inversion layer (Juvik and Ekern, 1978). Furthermore, fog droplets are scavenged by soil and vegetation in contact with the clouds. Some of this intercepted water contributes to aquifer recharge (Giambelluca and Sanderson, 1993).

Sample Collection

Water samples were collected between 28 July and 1 August 2008 from 18 locations (Table 5.1). Nine Hawaii Department of Water Supply drinking water wells (water supply wells), five brackish coastal ponds and wells, three coastal monitoring wells, and a lava tube that discharged to the bottom of Kailua Bay were sampled (Figure

Table 5.1: Sample name, location, collection date, water temperature (Temp), sample elevation (Elev), salinity (Sal), calculated recharge temperature, and calculated recharge elevation listed in order from north to south. All samples were collected in 2008.

^aLatitude and Longitude are relative to WGS84. Water supply well locations are withheld to comply with water resource protection guidelines; state designated well numbers are given instead of geographic location.

^bFor samples with two listed numbers, the first number corresponds to the calculated recharge temperature or elevation and the second number corresponds to the actual temperature or elevation used in the CFC models.

^cDepartment of Water Supply drinking water well.

^dKaloko-Honokohau (KAHO) National Historical Park observation well.

^ePuuhonua o Honaunau (PUHO) National Historical Park anchialine pool.

^fSamples likely had a fog drip component, causing the calculated recharge elevation to plot at a lower elevation than the actual sample location. The lower elevation of the main fog belt (975 m) was used for the recharge altitude and 17.3°C was used for the recharge temperature in the CFC models (see Recharge Altitude and Temperature).

^gEstimated recharge temperatures are warmer than sample temperatures at collection, suggesting a fog drip component. An elevation of 975 m was used for the recharge altitude and 17.3°C was used for the recharge temperature in the CFC models (see Recharge Altitude and Temperature).

5.1). All wells were purged before sample collection. Existing pumps installed in water supply wells were utilized to obtain samples from three basal and six high-level wells. Basal wells extended no greater than 15 m below sea-level. Open intervals in the wells ranged from 2 to 137 m. The three monitoring wells extended no greater than 5 m below sea-level and were sampled using a portable stainless-steel Fultz Pump equipped with

polyethylene tubing. Polyethylene tubing is traditionally considered unsuitable for CFC sampling because it releases low concentrations of CFC-11 and CFC-113 into the sample (Cook et al., 2006). We will discuss the implications of sampling with this tubing in the results and discussion sections. Coastal well and pond samples were collected using a peristaltic pump (geopump by geotech, Denver, CO) equipped with Viton tubing (Barnant MasterFlex, Thermo Scientific). Samples from these locations were collected by placing the end of the tubing as close as possible to spring vents or the bottom of the well or pond. Temperature and salinity measurements were taken at the time of sample collection using a multiparameter sonde (YSI Model 63; YSI Inc., Yellow Springs, OH) accurate to within $\pm 1\%$ for both temperature and salinity. Geographic position was determined using a hand-held GPS receiver (Garmin eTrex, Olathe, KS) with 15 m accuracy.

Oxygen and Hydrogen Isotopic Analysis of Water

Samples for oxygen and hydrogen isotopic analysis of water were collected in 20 mL glass vials (MicroLiter Analytical Supplies, Inc. #20-2300), filled from the bottom up, and sealed underwater with a rubber septum (MicroLiter Analytical Supplies, Inc. #20-0025) and aluminum crimp-top seal (MicroLiter Analytical Supplies, Inc. #20-0000A). At least three volumes of water flowed through each vial prior to sealing. Samples were analyzed at the University of Utah Stable Isotope Ratio Facility for Environmental Research (SIRFER). All oxygen and hydrogen isotopic data are expressed in ‰ notation relative to Vienna Standard Mean Ocean Water (VSMOW) on a normalized scale in which $\delta^2\text{H}$ of standard light Arctic precipitation (SLAP) water is -428‰ and $\delta^{18}\text{O}$ of SLAP water is -55.5‰ .

Establishing Recharge Altitude

Recharge elevations were estimated using the East Maui rain-shadow $\delta^{18}\text{O}$ /altitude gradient from Scholl et al. (2002):

$$\delta^{18}\text{O} = -0.00123m - 4.42 \quad (5.1)$$

where $\delta^{18}\text{O}$ is the measured oxygen isotopic composition of water and m is the calculated recharge altitude.

Salinity measurements were used to correct brackish samples for seawater content by employing simple mass balance rules. For this correction, brackish coastal wells and ponds were assumed to be a mixture of fresh meteoric water (salinity = 0) and seawater (salinity = 35 and $\delta^{18}\text{O} = +0.2\text{‰}$ relative to SMOW; Epstein and Mayeda, 1953).

Establishing Recharge Temperature

We calculated recharge temperatures using well-established lapse rates for the Hawaiian Islands (Nullet and Sanderson, 1993). Below 1,100 m, an average lapse rate of $7.3^{\circ}\text{C}/1,000$ m was applicable, while above 1,200 m, an average lapse rate of $4.1^{\circ}\text{C}/1,000$ m was relevant (Nullet and Sanderson, 1993). For each sample, we used the recharge altitude calculated from the $\delta^{18}\text{O}$ /altitude gradient to derive a recharge temperature based on the lapse rate equation above. For all lapse rate calculations, we used a mean annual temperature of 23.7°C for sea-level.

Chlorofluorocarbon Analysis of Water

Samples for CFC analysis were collected in 125 mL boston round glass bottles (Wheaton #217112) in triplicate. All bottles were filled from the bottom up, and at least three volumes of water overflowed the bottle before each sample was sealed under water using an aluminum foil-lined screw cap (Scientific Specialties #A69522). Bottles were inspected for large air bubbles after filling. If no large air bubbles were present, samples were double sealed using electrical tape and stored upside-down until analysis. Samples were analyzed at the University of Miami Rosenstiel School of Marine and Atmospheric Science (RSMAS) using purge-and-trap gas chromatography with electron capture detection (Bullister and Weiss, 1983; Happell et al., 1996), approximately one month after sample collection. CFC concentrations are reported on the Scripps Institution of Oceanography 1998 (SIO 1998) absolute calibration scale (Prinn et al., 2000). The detection limit for CFC-12 and CFC-113 was 0.010 pmol/kg and the limit for CFC-11 was 0.005 pmol/kg. Precision for all three CFCs was 2% or less. All CFC ages are apparent ages, but we use age for brevity. Age indicates the time elapsed since isolation of recharged water from the atmosphere. We also expressed our results as recharge years. As with the age, the recharge year indicated when the water was isolated from the atmosphere and reached the water table.

Establishing Chlorofluorocarbon Apparent Ages

Individual concentrations of CFC-11, CFC-12, and CFC-113 and ratios of CFC-12/CFC-11, CFC-113/CFC-12 and CFC-113/CFC-11 were used to calculate groundwater ages using well-established formulas and standard techniques described by Plummer and Busenberg (2006b). Briefly, the concentration of a particular CFC, C_i , dissolved in water and in equilibrium with air is proportional to the partial pressure, p_i , of the gas in the air:

$$C_i = K_H p_i \quad (5.2)$$

where K_H is the Henry's Law constant for C_i (Plummer et al., 2006a). All brackish samples were corrected for the salinity dependence of K_H (Plummer and Busenberg, 2006b). The p_i for C_i is defined by:

$$p_i = x_i(P - p_{H_2O}) \quad (5.3)$$

where x_i is the dry air mole fraction of C_i ($x_i \ll 1$), the total atmospheric pressure is P , and the water vapor pressure is p_{H_2O} (Warner and Weiss, 1985; Plummer et al., 2006a). The dry air mole fraction was then replaced with a dry air mixing ratio, volume per volume. The dry air mixing ratio of a particular CFC was compared to the appropriate historical atmospheric mixing ratio to determine a recharge year (Plummer et al., 2006a).

CFC ages were also determined from measured concentrations of two CFCs by well-established time-dependent atmospheric CFC concentration ratios. Briefly, if a fraction x of CFC-free water mixes with a fraction $(1-x)$ of CFC-containing water, then the concentrations of the CFCs, for example CFC-113 and CFC-12, are established by simple mass balance rules using:

$$[CFC-113]_{mixture} = (1-x)[CFC-113]_y \quad (5.4)$$

and

$$[CFC-12]_{mixture} = (1-x)[CFC-12]_y \quad (5.5)$$

where $[CFC-113]_{mixture}$ and $[CFC-12]_{mixture}$ are CFC concentrations in the water (determined from sample analysis), and $[CFC-113]_y$ and $[CFC-12]_y$ are concentrations of the CFC-containing fraction. The apparent age of the younger, CFC-containing water was determined by:

$$[CFC-113]_{mixture} / [CFC-12]_{mixture} = [CFC-113]_y / [CFC-12]_y \quad (5.6)$$

Once this calculation was complete, a mixing ratio was calculated by:

$$[CFC-113]_{mixture} / [CFC-113]_y = [CFC-12]_{mixture} / [CFC-12]_y \quad (5.7)$$

A similar process was followed for CFC-113/11 and CFC-11/12 ratios.

Results and Discussion

Recharge Altitudes

Groundwater recharge elevations and approximate recharge areas can be established from $\delta^{18}\text{O}$ /altitude gradients in field areas where sharp contrasts in elevation exist (Scholl et al., 1995). The oxygen isotopic composition of the water samples in this study varied from -7.2 to -2.3‰ while hydrogen isotopic composition varied from -46.4

to -11.7‰ (Table 5.2). The 5‰ variation in ^{18}O and the 35‰ variation in ^2H support the use of a $\delta^{18}\text{O}$ /altitude gradient to determine recharge elevations. Calibrating the area's $\delta^{18}\text{O}$ /altitude gradient required knowledge of the local meteoric water line (LMWL). A precisely defined LMWL for the Kona Coast, unfortunately, has not yet been established. Trade wind microclimates in the Hawaiian Islands do exert strong influences on $\delta^{18}\text{O}$ /altitude gradients (Scholl et al., 2002). Trade wind microclimates follow predictable and similar patterns within and between the islands (Scholl et al., 2002). Additionally, similar temperature/altitude gradients along the similar facing slopes of west Hawaii and west Maui suggest that use of the calibrated $\delta^{18}\text{O}$ /altitude gradient (eq. 5.1) could be applied to samples from the Kona Coast. We refer to all of our calculated recharge elevations (Table 5.1) as approximate recharge altitudes because of this assumption. We acknowledge that eq. 5.1 may over- or under-estimate recharge altitudes

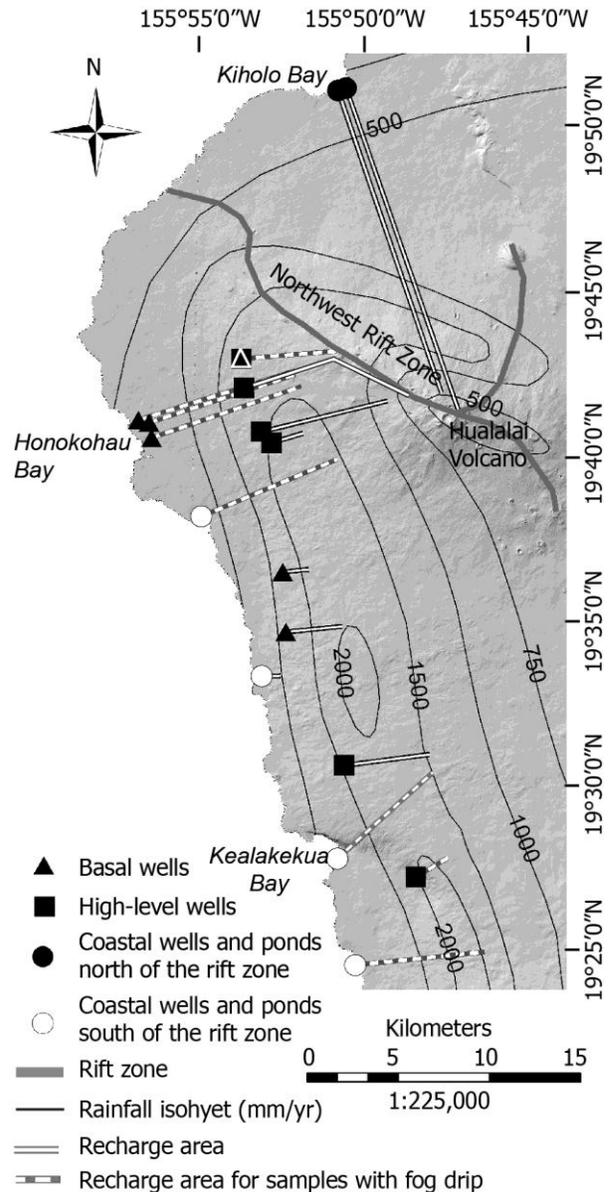

Figure 5.2: Recharge trajectories are shown as either solid white lines or dashed lines. Trajectories are drawn perpendicular to elevation contours (not shown). Samples with dashed lines likely have fog drip contributions. Trajectories for samples with fog drip are drawn to 975 m, which corresponds to the lowest elevation of the main fog belt zone. Rainfall isohyets (mm/y) are contoured on the map, showing areas of minimum and maximum precipitation. Rainfall data is available at: <http://hawaii.gov/dbedt/gis/download.htm>.

by several hundred meters because of the unique rainfall pattern along the Kona Coast. We have evaluated the limitations of applying eq. 5.1 to the Kona Coast by conducting a sensitivity analysis on our CFC results (see discussion below).

Approximate recharge elevations were drawn as straight line trajectories (Figure 5.2) from each sample location normal to elevation contours. Elevation contours above the sample from Hualalai necessitated a kink in the recharge trajectory on the steepest part of the mountain. This slope-normal method provided inferred recharge areas that were in good agreement with rift zone no-flow boundaries. The trajectories also indicated that most samples recharged from areas receiving maximum precipitation (Figure 5.2).

Measurements of fog drip from Mauna Loa by Juvik and Ekern (1978) and from Maui by Scholl et al. (2002) demonstrated that fog drip was a substantial component of recharging water in mountainous areas. Furthermore, Engott (2011) estimated that for Hualalai, the ratio of fog interception to rainfall was 0.3 above 1,500 m and 0.5 above 2,100 m. Fog drip contributions will cause approximate recharge altitudes to plot geographically down-slope of actual sample locations because eq. 5.1 was calibrated for the isotopic composition of precipitation. This geographic misalignment occurs because fog is isotopically enriched compared to precipitation. For example, Scholl et al. (2002) found that fog from the East Maui rain-shadow area was isotopically enriched in ^{18}O by 3‰ and ^2H by 21‰, compared to volume-weighted average precipitation at similar

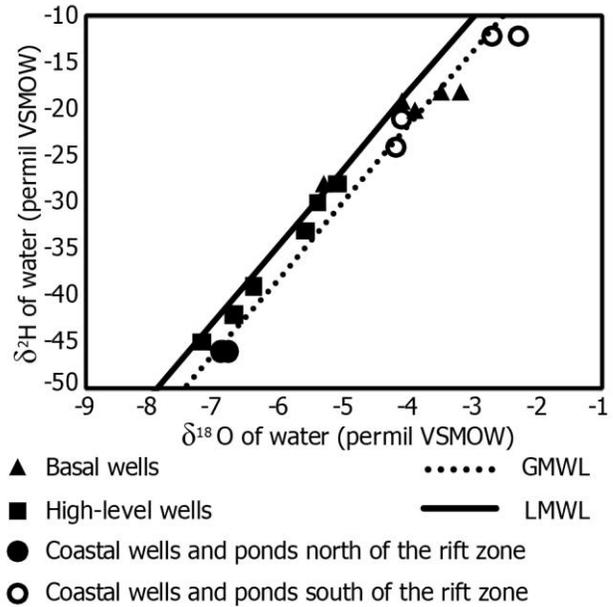

Figure 5.3: $\delta^2\text{H}$ versus $\delta^{18}\text{O}$ of water samples (uncorrected for salinity). Water supply (high-level and basal) wells plot on or just below the East Maui local meteoric water line (solid line). Error bars on the analyses are approximately the size of the sample symbols and are omitted for clarity. The global meteoric water line is shown for comparison (dotted line).

altitudes. The approximate recharge altitudes for Holualoa, PUHO, KAHO 2, and Kailua Lava Tube (Table 5.2), were impossibly low, plotting below sea-level. This result suggests that these samples likely had fog drip components.

Oxygen and hydrogen isotopic values of samples from Kona plotted on or slightly below the East Maui rain-shadow LMWL (Figure 5.3). Previous findings by Scholl et al. (2002) indicated that samples from the East Maui rain-shadow area were slightly enriched in ^{18}O compared to Hawaii rain-shadow samples. Results from this study indicated similar enrichment ($<0.25\%$). Brackish coastal wells and ponds plotted farther off the LMWL than freshwater samples. Salinity-corrected data did not show any evaporation trends.

Recharge Temperatures

On Oahu, recharging water temperatures closely track atmospheric temperatures (Mink, 1964). Since the Hawaiian Islands have similar climates, we assumed a similar relationship existed on Hawaii. Thus, we assumed that calculated atmospheric temperatures for each recharge altitude should have been similar to recharging water temperatures.

Calculated sample temperatures from the lapse rate equations are shown in Table 1. For Keei D, KAHO 1, KAHO 3, and Cameron's Well, estimated recharge temperatures were warmer than actual temperatures during sample collection. This relationship also held true for Holualoa, PUHO, KAHO 2, and Kailua Lava Tube mentioned above. This relationship was opposite of Mink's (1964) observation that Hawaiian groundwater warmed as it flowed from recharge to discharge areas. Mink (1964) described warming by absorption of heat resulting from resistance to flow. Furthermore, water recharging down-slope should be warmer than water recharging up-slope. The field area also likely has remnant heat from historic volcanic activity. The reverse relationship for the samples mentioned above may indicate that either our calculated recharge altitudes were too low, or that the samples contained a fog drip component. If our recharge altitudes were too low, then the difference between the sample altitude and the recharge elevation should have been fairly consistent for all samples. This difference varied from 293 to 537 m, with an average value of 397 ± 105 m for the samples with impossibly low approximate recharge altitudes. This result indicates

that eq. 1 may underestimate recharge altitudes in the Kona area by roughly 400 m. We believe that the 293 to 537 m range is not tight enough to fully substantiate this hypothesis. Furthermore, samples from Hind Well, Bakken Pond, and Hualalai would have had to recharge above the summit of Hualalai (2,521 m). Although, as we describe below, this may have been the case for the Hind Well and Bakken Pond samples, the geographic location of the Hualalai sample dictates that it must have recharged from the slopes of Hualalai Mountain. We, therefore, prefer the fog-drip contribution hypothesis. For all samples that likely contained fog drip, the lower elevation of the main fog belt (975 m), which roughly corresponded to maximum precipitation zones, was designated as the recharge altitude (Table 5.1). The corresponding calculated lapse rate temperature of 17.3°C was designated for the recharge temperature (Table 5.1).

Basal wells south of Keahuola QLT-1 recharged from ~1.4 to 3.1 km upslope of the sampling locations. High-level wells similarly recharged from ~2.1 to 4.7 km upslope of well locations. Three high-level wells north of Keahuola QLT-1 recharged along the flanks of Hualalai Volcano from 5.3 to 9.4 km upslope of the sample locations. The three southern-most coastal wells and ponds recharged predominantly within the main precipitation belt, from 1.0 to 8.1 km upslope of their geographic locations. The KAHO samples recharged from within the fog belt, 8.7 to 9.0 km upslope of the monitoring locations. Coastal samples north of the rift zone may have recharged from the upper flanks of Hualalai Volcano (17.6 to 18.7 km upslope), as shown in Figure 5.3. The recharge trajectory of these samples intersected the fog belt, although the isotopic and temperature data did not indicate a fog drip component. Since fog drip biases recharge elevations low, these samples may have alternately recharged from the lower flanks of Mauna Kea or Mauna Loa (Figure 5.1 inset). The recharge trajectories from Hualalai and Honokohau intersected the fog belt as well. The isotopic data from these samples also did not suggest the presence of a fog drip component. We hypothesize that the calculated recharge elevations from these samples may also be biased low.

Recharge trajectories for all KAHO samples (basal samples) showed water recharge from areas geographically above the four high-level wells on the flanks of Hualalai Volcano. Although the geographic locations of the high-level aquifers were not strictly defined in the field area, long recharge trajectories for the Kailua Lava Tube

sample, Cameron's well near Kealahou Bay, and the anchialine pool at PUHO may have also traversed the high-level/basal aquifer boundary. These relationships provide evidence that high-level water recharged the basal lens along the entire field area.

Most samples likely had a fog drip component, as suggested by the oxygen and hydrogen isotopic data, or had recharge trajectories that traversed the fog belt. Fog drip probably contributed to aquifer recharge and requires further assessment regarding its isotopic signature and its importance for aquifer recharge, relative to precipitation inputs.

Chlorofluorocarbons and the Unsaturated Zone

CFC water-based ages depend on equilibrium partitioning between recharging groundwater and the partial pressures of the three CFCs in the atmosphere when recharge occurs (Katz, 2004). Successful interpretation of CFC data, therefore, requires knowledge of each sample's recharge elevation and temperature, which were calculated (Table 5.1) using oxygen and hydrogen isotopic measurements, a $\delta^{18}\text{O}$ /altitude gradient, and well-established lapse rates for the Hawaiian Islands.

Implicit in this method is the assumption that CFC concentrations of the recharging water (at the top of the water table) were in equilibrium with atmospheric concentrations at the time of recharge (Busenberg and Plummer, 1992; Plummer and Busenberg, 2000; Plummer et al., 2000; Katz et al., 2001). This assumption necessitated fast gas exchange between tropospheric air and unsaturated zone air. Several circumstances likely facilitated fast gas exchange through the unsaturated zone along the Kona Coast: (1) highly permeable lava flows, (2) a complex network of fractures and lava tubes, (3) high recharge rates (2,000 mm/yr; Cook et al., 2006), (4) barometric pumping of air, and (5) thermally induced topographic wind driving gas transport through the unsaturated zone (Nilson et al., 1991). If our assumption of rapid gas exchange through the unsaturated zone was invalid, then groundwater ages would indicate equilibrium with old air (Plummer et al., 2006c), but not the actual time of recharge.

The Piston Flow Model for Chlorofluorocarbons

The piston flow model is commonly used for water age interpretation of CFC data. This model accounts for water of nearly uniform age that is approximated by flow through a pipe (Plummer and Busenberg, 2006b). The water does not mix

^aAll samples were analyzed in triplicate. Water concentration is corrected for stripping efficiency.

^bEquivalent atmospheric concentration calculated from measured water concentration and solubility functions found in Warner and Weiss (1985) and Bu and Warner (1995).

during transit from the recharge location to the discharge location (Plummer and Busenberg, 2006b). Steady-state conditions, one water source per sample, water travel at a mean velocity (Happell et al., 2006), negligible hydrodynamic dispersion, and negligible molecular diffusion (Katz et al., 2001) are other assumptions for this model. Relatively tight age agreement (within ~6 years; tighter is better) of all three CFC species suggests that the sample can be explained as being from one water source of uniform age.

Measured concentrations of the three CFCs in water as well as their equivalent atmospheric concentrations used for the piston flow model are given in Table 5.3. Figure 5.4 shows results for the piston flow model. The 5.5-year range for Halekii and the 6.0-year range for Keel D suggested that these samples were composed of water from one source that recharged between 1963 and 1968.5 for Halekii and between 1971 and 1977 for Keel D.

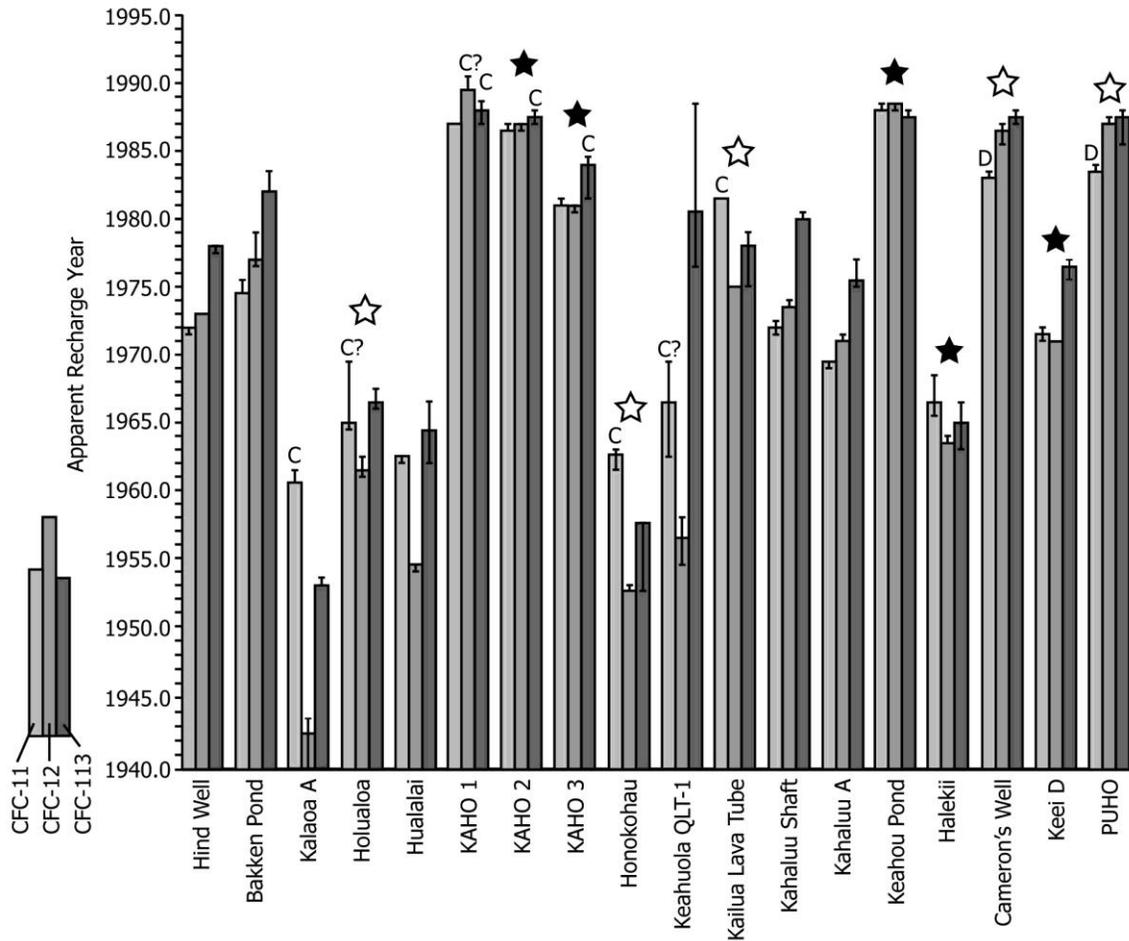

Figure 5.4: Piston flow model results for CFC-11, CFC-12, and CFC-113 delineated by sample. Each bar's height represents the median recharge year of the triplicate analysis. Lower and upper ends of the uncertainty bars represent minimum and maximum recharge years given by the triplicate analysis. CFC data lacking uncertainty bars yield concordant recharge years for all analyses of the sample. A (C) above a bar means sample contamination, a (C?) means potential sample contamination, and a (D) indicates sample degradation with the CFC represented by the bar. A black star above a sample indicates that the model can explain the data, whereas a white star indicates that the model can explain the data with additional assumptions (see discussion).

The more recent recharge year given by CFC-11 and CFC-12 than by CFC-113 (Figure 5.4) indicates that Honokohau, Kalaoa A, and potentially Holualoa, and Keahuola QLT-1 were contaminated with CFC-11. Ignoring CFC-11 contamination for these samples, the piston flow model for Holualoa and Honokohau gave recharge years between 1961 and 1967.5 and 1952.5 to 1957.5, respectively (Figure 5.4).

Relatively tight CFC-triplet agreement for Halekii, Keei D, and potentially Holualoa and Honokohau suggests that the high-level water in these wells could have been biased toward more permeable layers of the aquifer. Alternately, the part of the aquifers sampled could have contained consistently-aged water. We evaluated CFC ages of these samples by estimating horizontal hydraulic conductivity and comparing the conductivity results to published values. Meyer and Souza (1995) estimated that dike complexes have horizontal hydraulic conductivities ranging from 0.003 to 0.03 m/d. Marginal dike zones are transitional areas between dike complexes and dike-free areas. Marginal dike zones have estimated horizontal hydraulic conductivities ranging from 0.15 to 3.05 m/d (Oki, 1999). Lava flows in dike-free areas, away from rift zones, have the greatest estimated horizontal hydraulic conductivities (152 to 10,330 m/d; Kanehiro and Peterson, 1977; Nance, 1991; Oki et al., 1999). We used the recharge year from the piston flow model and the straight line travel distance determined from the recharge trajectory to estimate maximum horizontal hydraulic conductivities by the Pythagorean Theorem. This calculation assumed no tortuosity in the flow path. The aquifer above Holualoa had a maximum horizontal hydraulic conductivity of 0.3 m/d (calculated from straight trajectory; not kinked trajectory). The maximum horizontal hydraulic conductivity for Honokohau was 0.4 m/d, Halekii was 0.3 m/d, and Keei D was 0.2 m/d. Calculated hydraulic conductivities for these samples were comparable to the range given for marginal-dike zone areas (0.15 to 3.05 m/d; Oki, 1999). These maximum horizontal hydraulic conductivities were all comparable and were reasonable given that the exact locations of dike zones and marginal dike zones are unknown.

Water collected from Hawaii Department of Water Supply wells was sampled over large open intervals. The complex and imprecisely known geometry of aquifer systems in the area (Oki, 1999) make it unsurprising that the piston flow model only worked for several of the high-level samples.

All KAHO samples were collected using polyethylene tubing. This tubing contributed noticeable amounts of CFC-113 contamination. The CFC-11 and CFC-12 recharge years are indistinguishable from each other indicating that CFC-11 contamination was not detectable within the precision of the analysis (Figure 5.4).

Most coastal wells and ponds had recharge years in the 1970s and 1980s (Figure 5.4). The pond near Keauhou, KAHO 2, and KAHO 3 had extremely good recharge year agreement (late 1980s for all). Cameron's Well and the PUHO sample may have experienced CFC-11 degradation. Using only unmodified CFCs for these samples, recharge years ranged from 1985.5 to 1988.0. The Kailua Lava Tube sample was modeled by the piston flow model, providing that it had CFC-11 contamination. If contaminated by CFC-11, the water for this sample recharged to the aquifer between 1975.0 and 1979.

Maximum horizontal hydraulic conductivities for these samples were 1.1 and 1.0 m/d for KAHO 2 and KAHO 3, respectively, 0.1 m/d for Keauhou Pond, 0.7 m/d for Kailua Lava Tube, 0.8 m/d for Cameron's Well, and 0.9 m/d for PUHO. Except for Keauhou Pond, maximum horizontal hydraulic conductivities were greater than for the water supply wells. These results suggest that the coastal samples flowed through more permeable and less dike-compartmentalized aquifers, compared to the water supply wells. The calculated hydraulic conductivities, however, do not approach estimates for dike-free areas of 152 to 10,330 m/d (Kanehiro and Peterson, 1977; Nance, 1991; Oki et al., 1999).

Bakken Pond and Hind Well had similar recharge altitudes that traversed the fog belt. The estimated recharge temperatures were too low for these samples to be modeled using the Piston Flow model. An alternate explanation of the data required contamination by CFC-113 and degradation of CFC-11 (Plummer et al., 2006c) to apply the piston flow model. These results strongly suggest that the samples could not be from water of uniform age.

Water recharged at high altitudes had lower dissolved CFC concentrations (caused by lower barometric pressure) than water recharged at lower altitudes. Uncertainties on recharge altitudes can cause large uncertainties on groundwater ages. Since our samples recharged at higher altitudes in this mountainous region, large over- or under-estimations ($\pm 1,000$ m) in recharge altitude would bias the age toward: (1) older values if elevation was underestimated or (2) younger values if elevation was overestimated. Large elevation uncertainties were unlikely for many locations, but may have been possible for samples with fog drip. To assess the uncertainties on samples with likely fog drip, we performed a sensitivity analysis on all calculated recharge dates.

Our analysis included temperature and elevation ranges from 11.7°C at 2,255 m (top of fog belt) to the elevation and corresponding temperature at each sample's collection location. Calculated recharge ages were accurate to within ten years for the piston flow model. This sensitivity analysis performed over the large altitude gradient also incorporated the uncertainty associated with use of eq. 1 to calculate recharge altitudes.

When the CFC-113 recharge date is more recent than the CFC-11 and CFC-12 recharge date, mixing of two water sources is qualitatively demonstrated (Plummer et al., 2006b). This pattern exists for Bakken Pond, Hind Well, Holualoa, Hualalai, Keahuola QLT-1, Kahaluu Shaft, Kahaluu A, Cameron's Well, Keei D, and PUHO. Of these samples, Cameron's Well, Keei D, and PUHO were successfully modeled using the piston flow model (Figure 5.4).

The Binary Mixing Model for Chlorofluorocarbons

The binary mixing model used a simple mixture of two end-member waters, where one recently recharged and the other recharged in the more distant past (Happell et al., 2006). Theoretically, the end-members can be any age (Happell et al., 2006). Our model assumed one end-member recharged prior to 1940 (free of CFCs), and the other recharged since the 1940s (contains CFCs). Ratios of one CFC concentration to another (CFC 113/12, CFC 113/11, and CFC 11/12) were used to differentiate groundwater ages for this model. Binary mixing models best explain the data if all three CFC ratios have similar fractions of recently recharged water (Plummer et al., 2006b). Since the recharge year is nearly independent of the mixing ratio for the two water components, the age of the CFC-containing fraction is represented by the concordance of its three CFC ratios (rather than by absolute abundances), provided that the old water is CFC-free (Plummer et al., 2006b). Within this approach, ratio-based ages are not calculable when: (1) the apparent age is not contained within the applicable dating range for a particular CFC ratio, (2) the CFC ratio of a water sample is greater than the largest ratio recorded in the atmosphere, and (3) the CFC ratio of a water sample is smaller than the smallest CFC ratio recorded in the atmosphere. For our results, such non-calculable ratio-based ages are noted as NP (not possible) in Table 5.4. For instances where CFC-11 contamination occurred, fractions of young water were typically calculated using CFC113/12 ratios.

Table 5.4: Sample names, apparent CFC recharge years for the piston flow and binary mixing models. Calculated fractions of young water are given as well as the CFC ratio used to calculate the fractions for all samples, listed in order from north to south.

NP - The ratio-based age is not possible for one of several reasons (see Results and Discussion).

Similar fractions of recently recharged water for Holualoa, Hualalai, Honokohau, Kahaluu Shaft, Kahaluu A, Halekii, and Kei D (Table 5.4) showed that the simple binary mixing model could be used for these samples, as illustrated in Figure 5.5. Water samples from these seven supply wells likely represented a part of the aquifer where flow lines of relatively old, CFC-free water converged with relatively young, CFC-containing water. All samples had young fractions of water that recharged between the late 1970s to late 1980s at the time of sample collection. The results illustrated that samples from these wells varied from 5 to 47% young water, with the remainder recharging prior to the atmospheric release of CFCs. The northernmost water supply wells (Holualoa, Hualalai, and Honokohau), which were closer to the Hualalai rift zone, contained a larger percentage of old water than the more southern wells. This relationship may indicate lower hydraulic conductivities and slower water movement through the presumably more heavily dike-compartmentalized aquifers near the rift zone. Burton et al. (2002) noted,

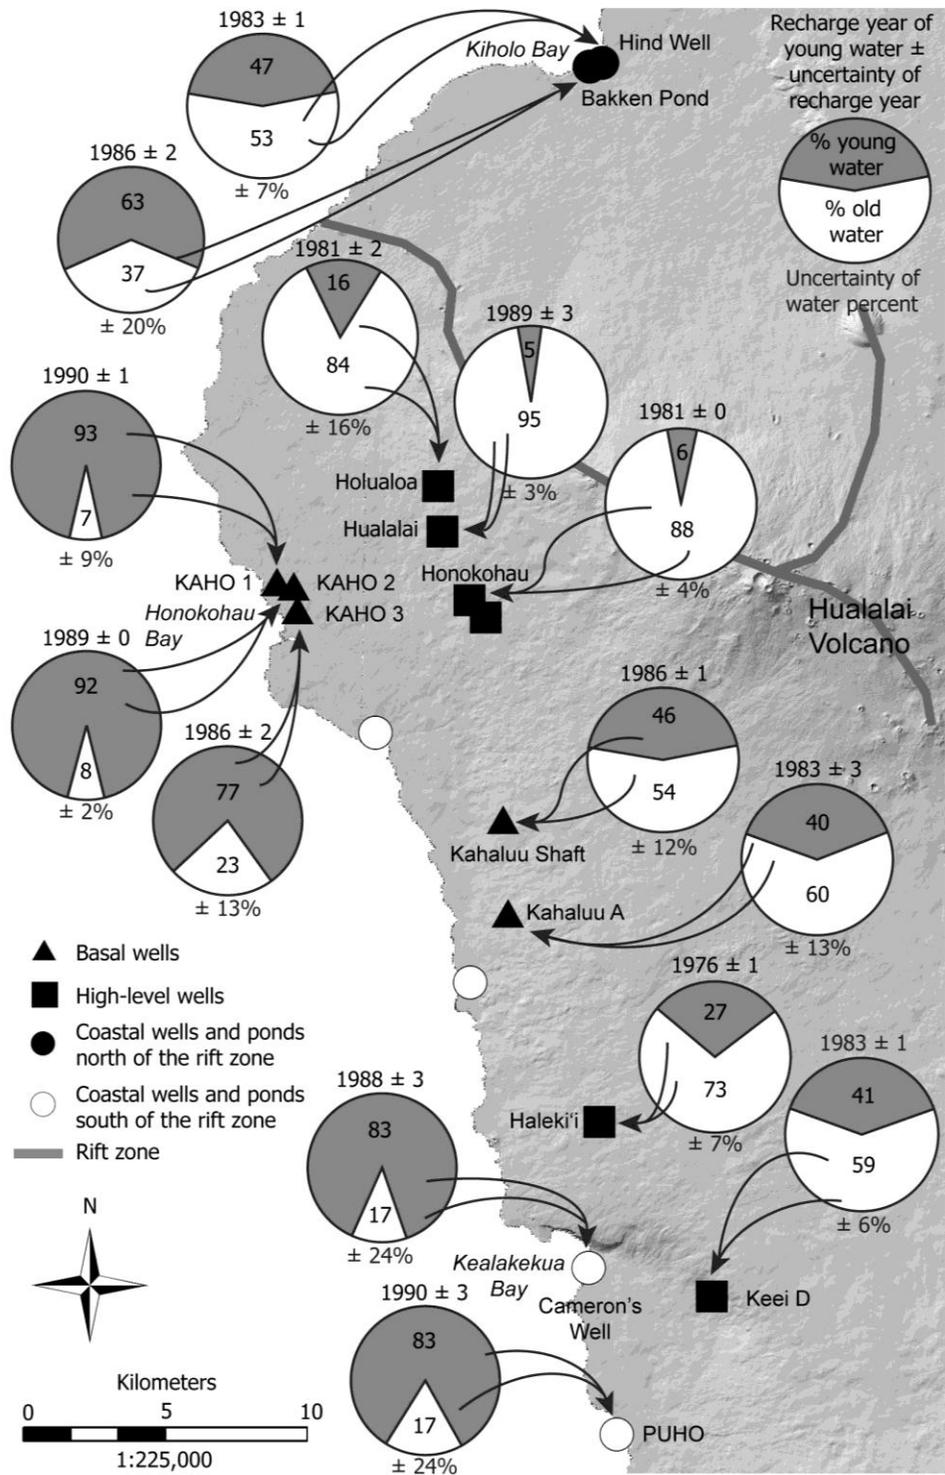

Figure 5.5: Pie graphs showing binary mixing model results. Recharge years above each pie represent the recharge year of the young fraction of water plus the uncertainty on the recharge year. Gray portions of each pie show the percent of young, CFC-containing water in each sample. White portions of each pie show the percent of old, CFC-free water (recharged before 1940). Percent signs underneath each pie represent the uncertainty on the percentage of young and old water shown in the pie.

however, that the sampling process can produce mixtures of groundwater. Since our samples were drawn from wells with large open intervals (2 to 137 m) in fractured rock aquifers, mixtures may have been produced. Mixtures would cause the age of the young water to be biased old and the age of the old water to be biased young as described by Cook et al. (2006).

Coastal well and pond samples were also modeled using the simple binary mixing model. The KAHO samples, PUHO, and Cameron's well were dominated by mid-1980s to mid-1990s recharged water with smaller fractions (8 to 20%) of CFC-free water (Figure 5.5). We previously demonstrated that the Bakken Pond and Hind Well samples were mixtures of water of different ages. Averaging the nine fractions of young water (Table 5.4), Bakken Pond had ~63% mid- to late-1980s water, and although less robust, Hind Well had ~47% early- to mid-1980s water.

Our findings suggested that the top of the basal lens near the coast was fairly uniform in age. Coastal well and pond samples located in proximity to each other had similar patterns of CFC degradation or contamination, suggesting strong local land-use or aquifer controls influencing the samples. For example, the KAHO samples all likely had a fog drip component. Bakken Pond and Hind Well both recharged from the highest altitudes of all samples.

Travel Distance and Water Age

Samples with longer straight-line travel distances from their approximate recharge areas to water sampling depth generally had greater fractions of water recharged prior to 1940 (Figure 5.6). Water supply wells had a strong correlation ($r^2=0.94$) between percent young water in the sample and straight-line travel distance.

The maximum water travel distance

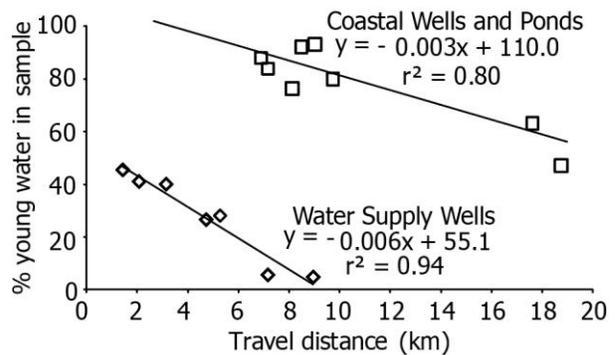

Figure 5.6: Relationship between (1) the percent of young water in the water supply well samples and (2) all other coastal well and pond samples relative to the straight line distance a water droplet would travel from the land surface to a well's pump or the sampling depth for coastal wells and ponds.

for water supply wells was less than 10 km, possibly constraining high-level aquifer compartment sizes. Basal water supply wells also plotted on high-level water curve, suggesting that basal water may have been highly influenced by water leakage from nearby dike compartments. An alternate, albeit fortuitous possibility is that the perforated casing depths of all basal wells intersected a mixture of young and old water of appropriate proportions to fall on the trend line with high-level wells.

Although less robust ($r^2=0.70$), the linear relationship from coastal well and pond samples tracked fairly closely to 100% young water at a sampling distance of zero meters. Coastal samples from the top of the basal aquifer were likely influenced by local and recent recharge. Since none of our coastal samples contained 100% young water, flow lines of older water within the aquifer must have been thin and were intersected during the sampling process.

Distinguishing Water Masses

Young fractions of water from the three CFC species are presented on a ternary plot shown in Figure 5.7. We converted modern fractions of water (determined by the CFC binary mixing model) into percentages. As described in Darling et al. (2010), water equilibrated with modern air resides at the center of Figure 5.7. Plotting the samples in this manner separates water masses containing similar fractions of recently recharged water by CFC compound and suggests that samples from basal and high-level areas can be distinguished. Figure 5.7 shows that high-level water resides in the area dominated by young water fractions from CFC-11, while basal water resides at the base of the triangle, within and below the modern air-equilibrated area.

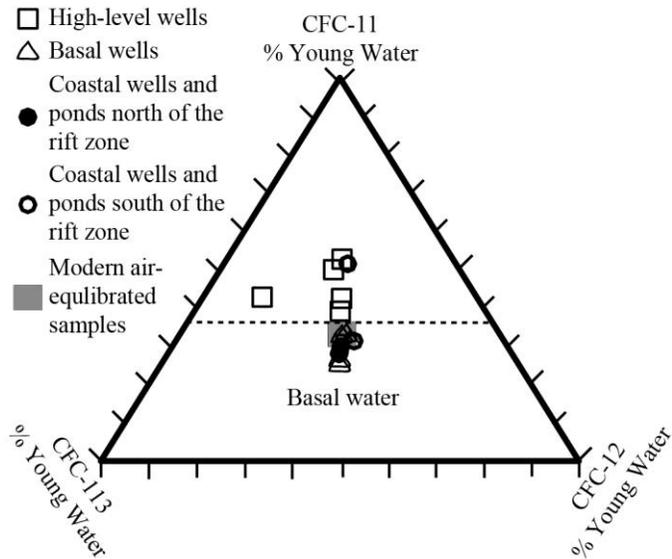

Figure 5.7: Ternary diagram showing normalized fractions of young water for each sample. The dashed line separates basal samples from high-level samples.

Figure 5.7 suggests that Keei D, which is considered a high-level water sample, has CFC signatures indicative of basal water, and therefore, may need to be reclassified as a basal water source. Furthermore, the sample from Kailua Lava tube had CFC signatures indicative of high-level water. This relationship suggests that water discharging from the bottom of Kailua Bay traveled through the basal aquifer without readily mixing with basal water. This finding suggests that high-level water can discharge directly to the ocean, bypassing the basal aquifer. Such flows may exist in other areas with conduit flow through high permeability features such as lava tubes.

Precipitation Patterns

Rainfall varies over time and, in the Hawaiian Islands, is impacted by the El Niño-Southern Oscillation (ENSO), the Pacific Decadal Oscillation (PDO), longer-term trends that may result from global warming, and possibly the recent volcanic activity at Kilauea Volcano (Giambelluca et al., 2011).

The effects of ENSO in the Hawaiian Islands are strong, with El Niño and La Niña events recurring roughly every 3 to 7 years. ENSO gives rise to large year-to-year variability in rainfall (Giambelluca et al., 2011). The PDO also exerts strong influences on rainfall patterns in Hawaii, with phases lasting up to 30 years. Since roughly the late-1970s, the PDO has been in a positive phase. Positive PDO phases are generally associated with lower rainfall in the Hawaiian Islands (Giambelluca et al., 2011). In addition to large changes in precipitation quantity caused by ENSO and PDO, rainfall in Hawaii has slowly declined over the past 90 to 100 years (Giambelluca et al., 2011).

In the Kona area, groundwater recharge increases with greater precipitation and decreases with lower precipitation (Engott, 2011). We can, therefore, hypothesize that the decrease in precipitation over the past century will cause groundwater discharge to the coastal areas to decrease over the next 30⁺ years as water recharged within the past 30 years slowly travels toward the coast.

Land-Use Changes

Since the binary mixing model suggests that young fractions of water recharged the aquifers in the area between the late-1970s to mid-1980s, we briefly discuss land-use changes since the mid-1970s. The study area's land-use in 1976 was dominated by

evergreen forested-land and rangeland, with smaller amounts of agricultural land, bare exposed rock, and urban land (<http://hawaii.gov/dbedt/gis/download.htm>). Urban development has increased rapidly over the past few decades in the Kona area. Urbanized land cover, for example, increased by more than 60% between 1992 and 2010 (<http://cie.research.yale.edu/research/land-use-and-land-cover-phase-ii>). These land-use changes coupled with increased population growth should decrease the quantity of groundwater reaching the coast and alter the nutrient biogeochemistry of the discharging groundwater. The more-immediate impacts of land-use changes on SGD in the Kona area have been studied by Dollar and Atkinson (1992), Johnson (2008), and Knee et al. (2010). However, more research is needed to understand how past land-use changes may impact future SGD, with specific attention paid to how urbanization has impacted and may impact the quantity and quality of the discharging groundwater.

Conclusions

Calculated recharge elevations show that many samples recharge from zones of maximum precipitation. The recharge trajectories and CFC data suggest that high-level water recharges the basal aquifer. Furthermore, water samples with substantial fog drip components are suggested by O and H isotopic data. The quantity of samples potentially influenced by fog drip demonstrates that fog drip requires a more detailed study, especially for the Kiholo Bay area where recharge trajectories are ambiguous.

CFC apparent age dating is applicable in the fractured-rock aquifers of west Hawaii. Distinct and robust correlations of fractions of percent young water versus travel distance exist for the water supply wells and the coastal wells and ponds. Such correlations may be useful for constraining sizes of dike compartments. Furthermore, a ternary plot of young fractions of recharging water suggests that it is possible to differentiate between water from high-level aquifers and water from basal aquifers. Our CFC work suggests that the Kailua Lava Tube sample is from high-level water sources, despite discharging to the bottom of a bay. Numerous lava tubes and conduits conducive to groundwater flow likely exist on the Hawaiian Islands. CFCs should be utilized more rigorously in such locations to confirm these results and to hopefully determine sources of water within the conduits.

Results presented here are useful for water supply managers and for those concerned with coastal ecosystems influenced by submarine groundwater discharge. Knowing aquifer residence times will allow for predictions about when recharged water masses may be expected to discharge to the sea and impact (positively or negatively) coastal ecosystems. Such studies are applicable in other field areas where long-term trends or changes in groundwater resources need to be understood.

CHAPTER 6. CONCLUSIONS

Accomplishments and Scientific Advancements

The aerial thermal infrared (TIR) technique is preferred over the satellite TIR technique because satellite data lack the spatial resolution necessary to detect submarine groundwater discharge (SGD) on the scale that it is normally observed. It is important to locate even small-scale SGD occurrences, especially in areas without streams, because SGD can deliver large quantities of dissolved nutrients and other constituents to the coastal zone. TIR imagery provides the information necessary to assess SGD on a regional scale, to choose field sites based on the imagery (minimizing field time spent searching for SGD), and to make informed designs for field studies that fit the scale of the SGD occurrences.

The complete methodology for the aerial TIR technique described within this dissertation encompasses data collection through post-flight data processing and image interpretation. I have demonstrated that this technique is an excellent way to locate SGD on a regional scale, thereby fulfilling my first research objective. These methods, I hope, will make aerial TIR missions accessible to more scientists interested in studying SGD. I also foresee this method branching out into other areas of research involving thermal contrasts, including geothermal activity, estuary dynamics, coastal currents, power plant and waste water outfalls, and the impacts of surface waters in estuaries, including water mass mixing.

I have demonstrated that use of ^{222}Rn for surface water and water-column surveying is beneficial for calculating groundwater fluxes. I have also shown that these surveys are useful for determining if multiple SGD locations are present at a single field location. I specifically recommend water-column surveying using ^{222}Rn in dynamic places like estuaries where multiple inputs of SGD may occur at different depths.

I have also demonstrated that ^{222}Rn mass balance models can be used to show where groundwater discharge occurs in Pearl Harbor on a segment-by-segment of coastline basis. My application of nutrient end-members to the ^{222}Rn model has allowed me to calculate nutrient budgets to the harbor on a segment-by-segment of coastline basis as well. The use of ^{222}Rn models to help estimate nutrient fluxes is applicable to other shorelines, and will prove useful for studying locations that require detailed knowledge

about where groundwater is discharging, as well as the quantity of dissolved compounds in the groundwater.

My research has greatly benefited from the combined use of aerial TIR remote sensing and ^{222}Rn surveying. The aerial TIR imagery stream-lined the field work by identifying where SGD occurred and, therefore, where to target field investigations. ^{222}Rn surveying corroborated TIR findings and can be used to detect SGD below the water's surface. Furthermore, groundwater plume areas calculated from TIR surveys have been extremely beneficial for ^{222}Rn mass balance modeling of all ^{222}Rn time-series measurements of point-source SGD in my field area. Another benefit, and a scientific advancement for the combined use of ^{222}Rn mass balance models and aerial TIR plume areas, is confirmation of a linear correlation between the two techniques that can be used to up-scale SGD flux estimates to the field region. This correlation will make complete assessment of SGD to a field area less time-consuming since only a few plumes need to be measured by ^{222}Rn mass balance. This research has proven that aerial TIR remote sensing and ^{222}Rn measurements identify similar SGD occurrences. This research has also fulfilled my second objective, which was to quantify groundwater and nutrient fluxes to Pearl Harbor.

I have measured the combined nitrogen and oxygen isotopic composition of dissolved nitrate from water supply wells, coastal springs, and estuary waters in the Pearl Harbor area. My third objective was to determine sources of nitrate to the aquifer and processes occurring along the flow path from recharge areas to discharge areas. This research has contributed knowledge about the Southern Aquifer Flow System on Oahu, which partially discharges into Pearl Harbor.

Many SGD studies are concerned with finding and quantifying SGD. However, they do not always attempt to understand what happens in the aquifer geographically upslope of SGD sites. I have made a first step toward investigating the linkage between recharged groundwater and the water that eventually discharges to the coast along entire groundwater flow paths by calculating groundwater residence times. Establishing water residence times allows inference about how land-use changes through urbanization, increased agricultural demands, or vegetation shifts due to climate change, for example, may impact the groundwater resources. Furthermore, changes in precipitation patterns

influence recharge quantities and the amount of water that can be pumped from aquifers. With respect to SGD, if we know how long it takes water to travel from recharge areas to the coast, say 30 years, we can assess how land-use changes in the last 30 years may impact SGD for the next 30 years. The same thought can be applied to SGD fluxes, which are dependent on water recharge.

My research in Kona demonstrated that the combined use of oxygen and hydrogen isotopes of water, $\delta^{18}\text{O}$ /altitude gradients, and well-established lapse rates do provide information about the recharge altitude and temperature of a water sample. From this information, inferred recharge trajectories can be established. This technique can be applied to any terrain that has steep altitude gradients. I have also shown that CFCs can be used in more pristine environments to learn about water residence times, again fulfilling the third objective of my research. I also suggest that CFCs can possibly be used to determine if a water sample originated from basal or high-level aquifers, providing valuable information about water mass mixing and the nature of the aquifers in the area.

Future Research

Thermal Infrared Remote Sensing

I spent a considerable amount of time characterizing radiance anomalies that were not related to submarine groundwater discharge processes, but yet, had temperature signals similar to groundwater discharge. It would be beneficial to develop a more quantitative approach for identifying and characterizing radiance anomalies so that it is less cumbersome to interpret sea-surface temperature maps from aerial TIR remote sensing.

Radon Measurements in Pearl Harbor

There are two major areas for future research in Pearl Harbor that expand on the research presented within this dissertation. First, subaerial springs experienced degassing of radon, which greatly influenced our ability to calculate water fluxes to Pearl Harbor. A detailed investigation of where springs are specifically located along stream segments would be highly beneficial for evaluating how much degassing of radon actually occurs before spring-fed streams reach Pearl Harbor. Second, several areas in Pearl Harbor were

found to have groundwater discharge from the bottom of the harbor (for example, at the back of Middle Loch) or from intermediate depths along the sides of the Harbor (for example, in West Lock by the W4 pier). These discharges warrant further investigation.

Nitrogen and Oxygen Stable Isotope Analyses of Dissolved Nitrate in Pearl Harbor

Stable isotope analyses of dissolved nitrate in the Pearl Harbor area need to be revisited with a more rigorous sampling approach and much better quantification of potential groundwater end-members. I think the approach has great potential for the Pearl Harbor area, especially since the land-use practices around the periphery of the harbor are quite different. I think future research would benefit from sampling of additional tracers to help characterize end-members and water masses. Combining stable isotope analyses of dissolved nitrate with stable isotope analyses of oxygen and hydrogen of the water molecules, for example, may be one way to better characterize end-members and, potentially, water mixing within the estuary.

Chlorofluorocarbon use in the Kona Area

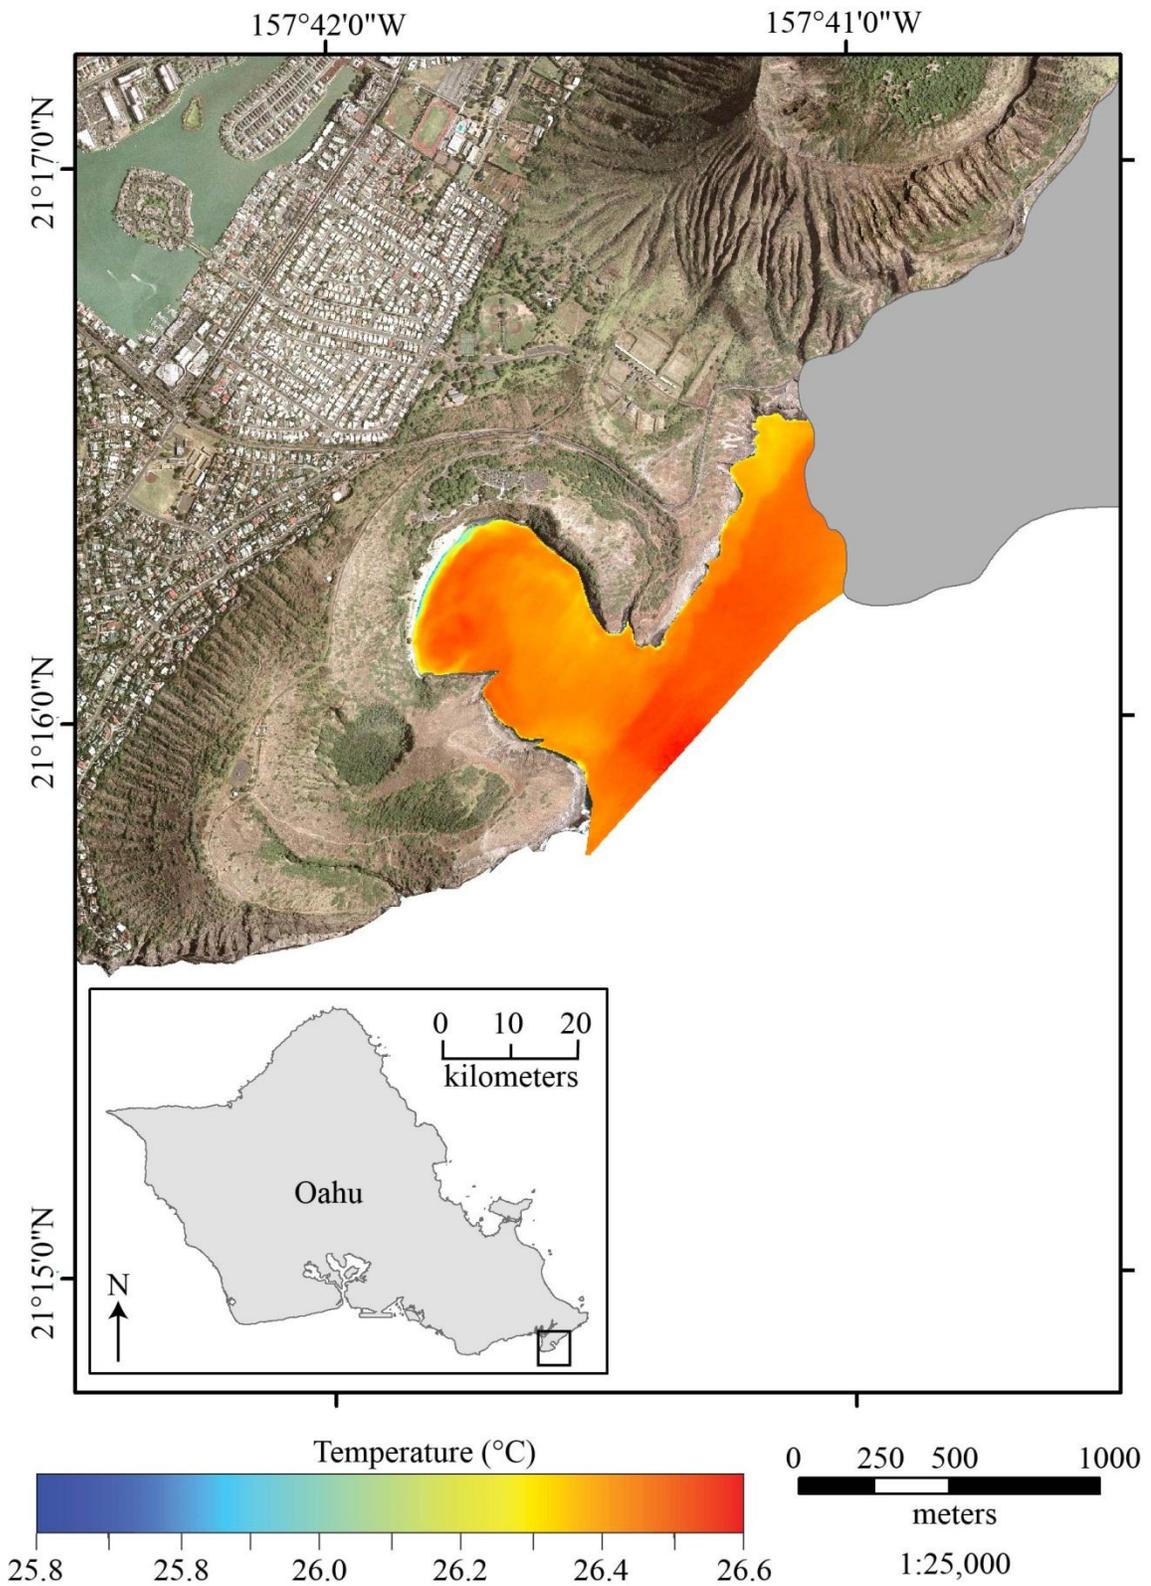

The lack of a local meteoric water line (LMWL) for Kona, Hawaii has complicated interpretations of stable isotope data for the area. A LMWL needs to be established for the Kona area for several reasons. The Kona area is the only place in the Hawaiian Islands with rainfall maxima in the summer. Scientifically speaking, it would be very interesting to see how the LMWL differs from other LMWLs established for the Hawaiian Islands. From a resource management perspective, it is beneficial to understand where aquifer water actually recharges, especially as population increases. Population growth will cause increased demands on the aquifer and increased likelihood for anthropogenic contamination of the aquifer and coastal waters. Furthermore, the recharge areas for groundwater flowing into the Kiholo Bay area, which has the largest known groundwater discharge fluxes on the Kona coast, need to be investigated more thoroughly.

I have shown that it may be possible to identify water sample origin (basal or high-level) through use of CFCs in the Kona area. This relationship needs to be confirmed by a study with a larger sample size. If confirmed, does the relationship hold true for the other islands? Additionally, if the relationship holds true, then coastal

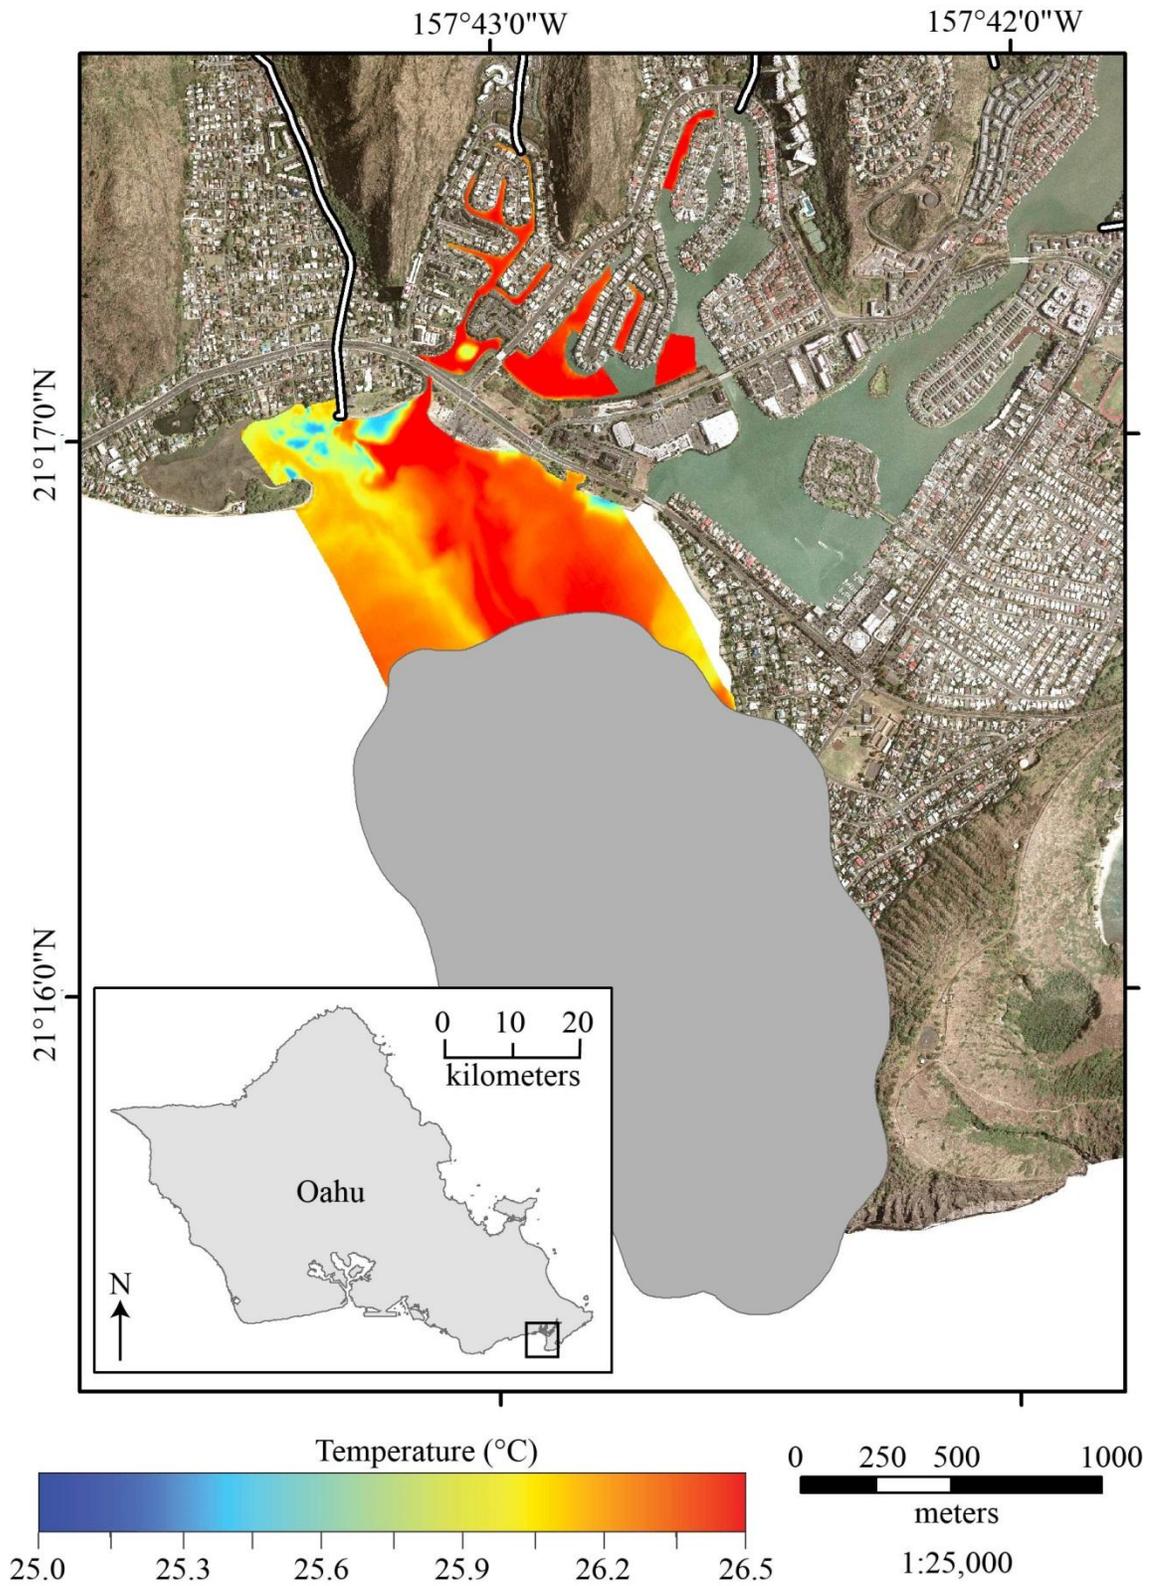

discharge locations that potentially travel through lava tubes and other conduits of preferential flow should be sampled. A rigorous evaluation of whether groundwater discharge at the coast really can originate from the high-level aquifer area is necessary. The sample from Kailua Bay indicates that this may be possible

APPENDIX 1. THERMAL INFRARED IMAGERY OF OAHU

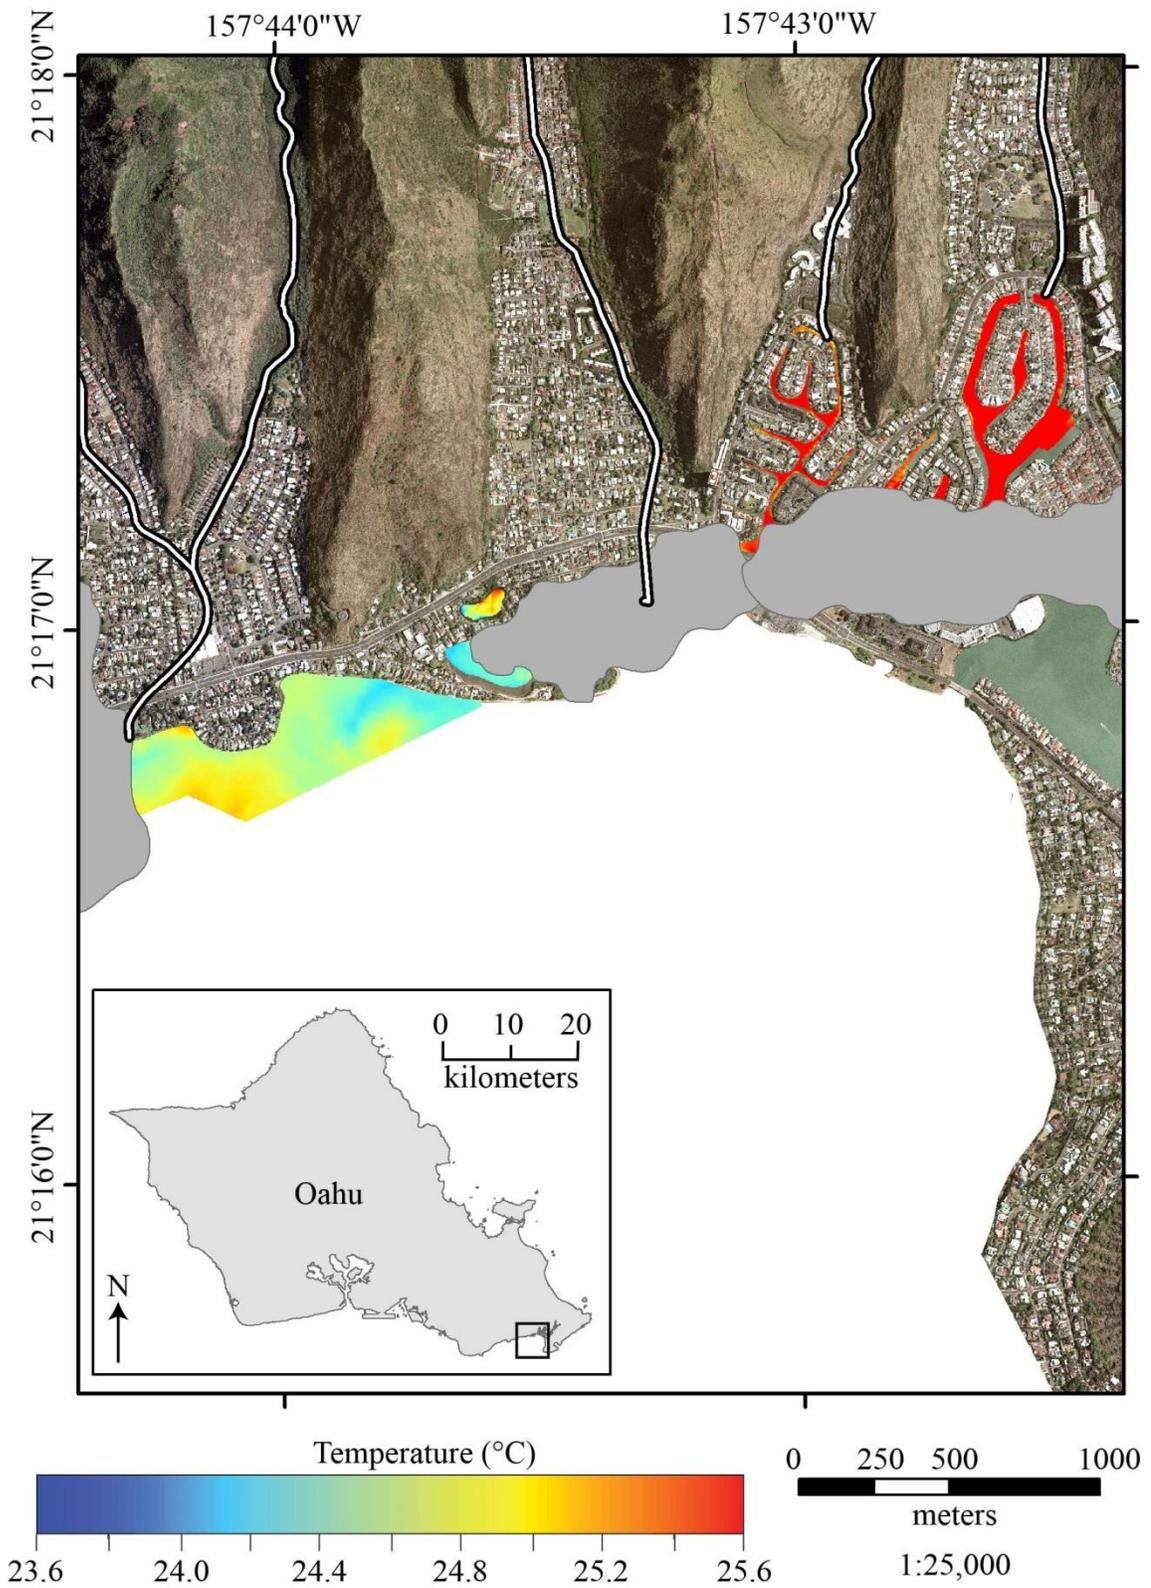

Processed thermal infrared imagery of Oahu, Hawaii are provided in this appendix as panels. All imagery is shown at the same map scale; however, temperature bars are maximized for contrast for each panel, and therefore vary from panel to panel. The panels begin at Hanauma Bay and move around the island in a clock-wise direction up to Kahuku Point. Data are unavailable from Kahuku Point to Makapuu Point. All data were collected on 12 June 2009, 6 July 2009, 17 July 2009, or 22 July 2009 between midnight and 07:00 a.m., Hawaii Standard Time (HST). Flight dates and collection times are given in each panel's caption. Since submarine groundwater discharge fluxes vary with tidal height, figure captions also contain tidal height information calculated relative to Honolulu Harbor (National Oceanic and Atmospheric Administration tide gauge 1612340) for easy comparison between multiple flights of a particular area and possible future data. In all panel captions, mean-lower low-water is abbreviated MLLW. No attempt is made to calculate actual tidal heights for distal areas that have different tide conditions from Honolulu Harbor.

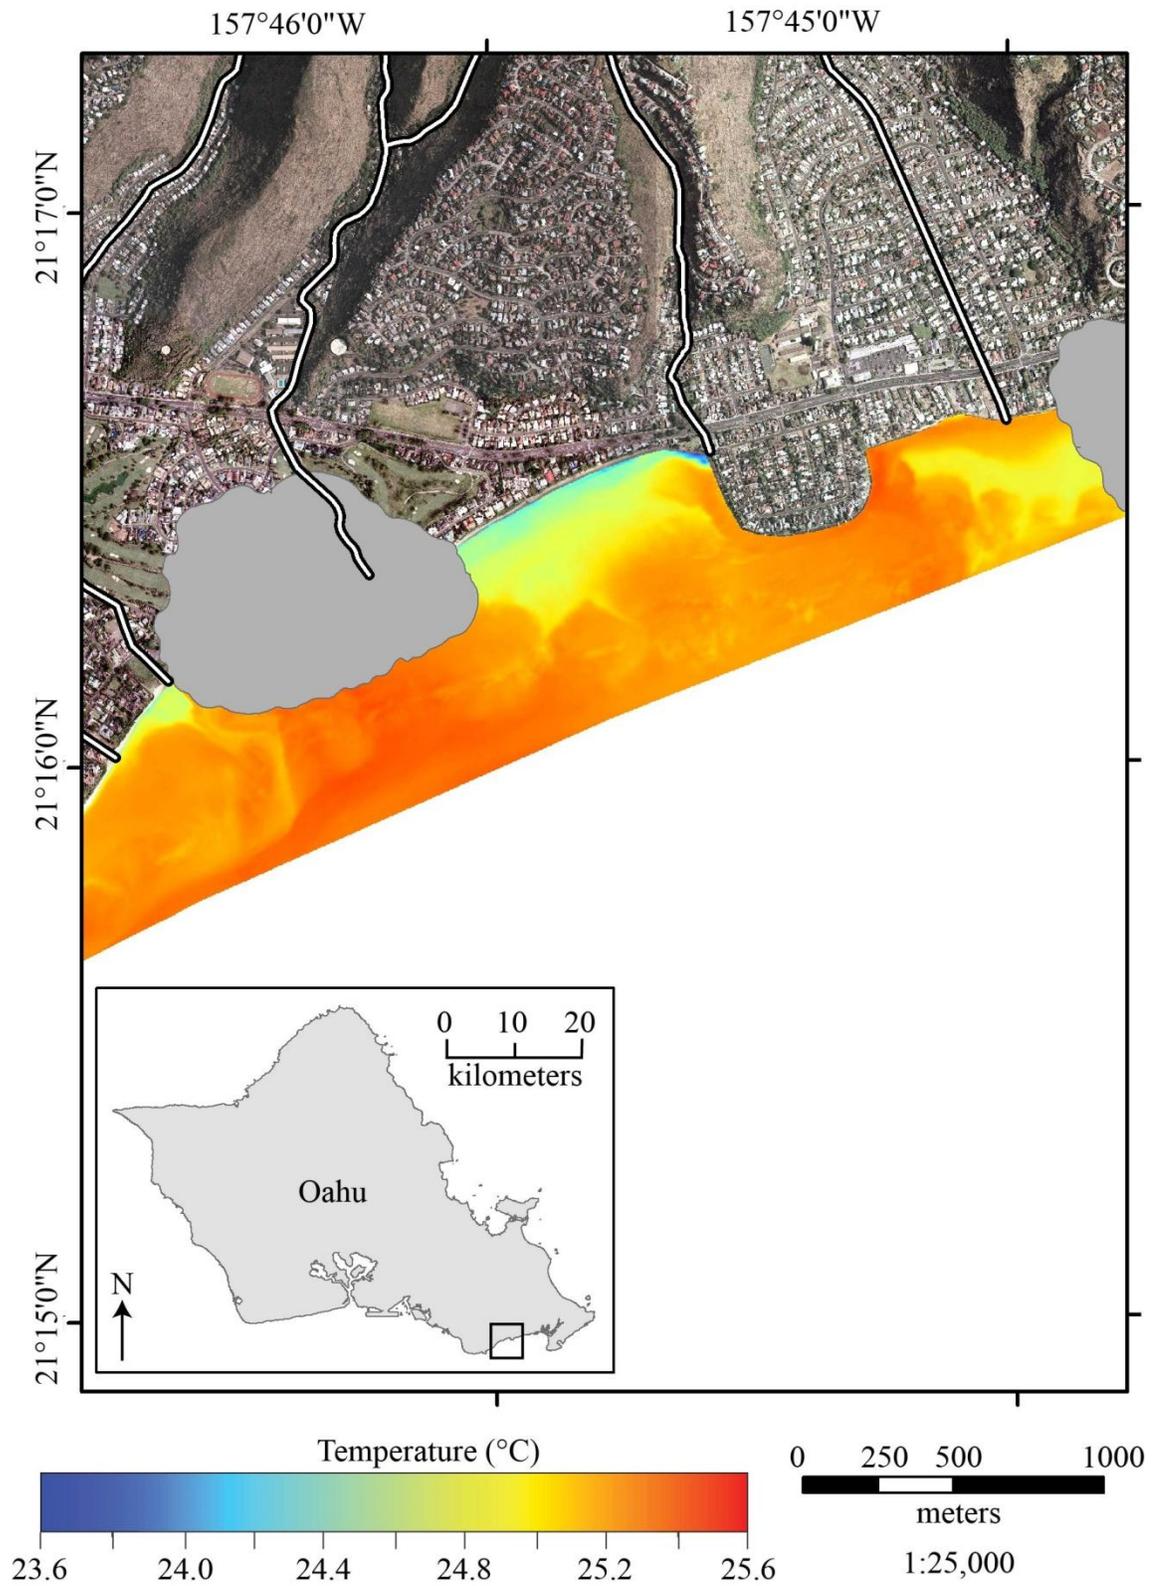

Panel 1: Hanauma Bay from 22 July 2009 at 01:31-01:34 a.m., HST. Honolulu tide was +0.12-0.13 m MLLW.

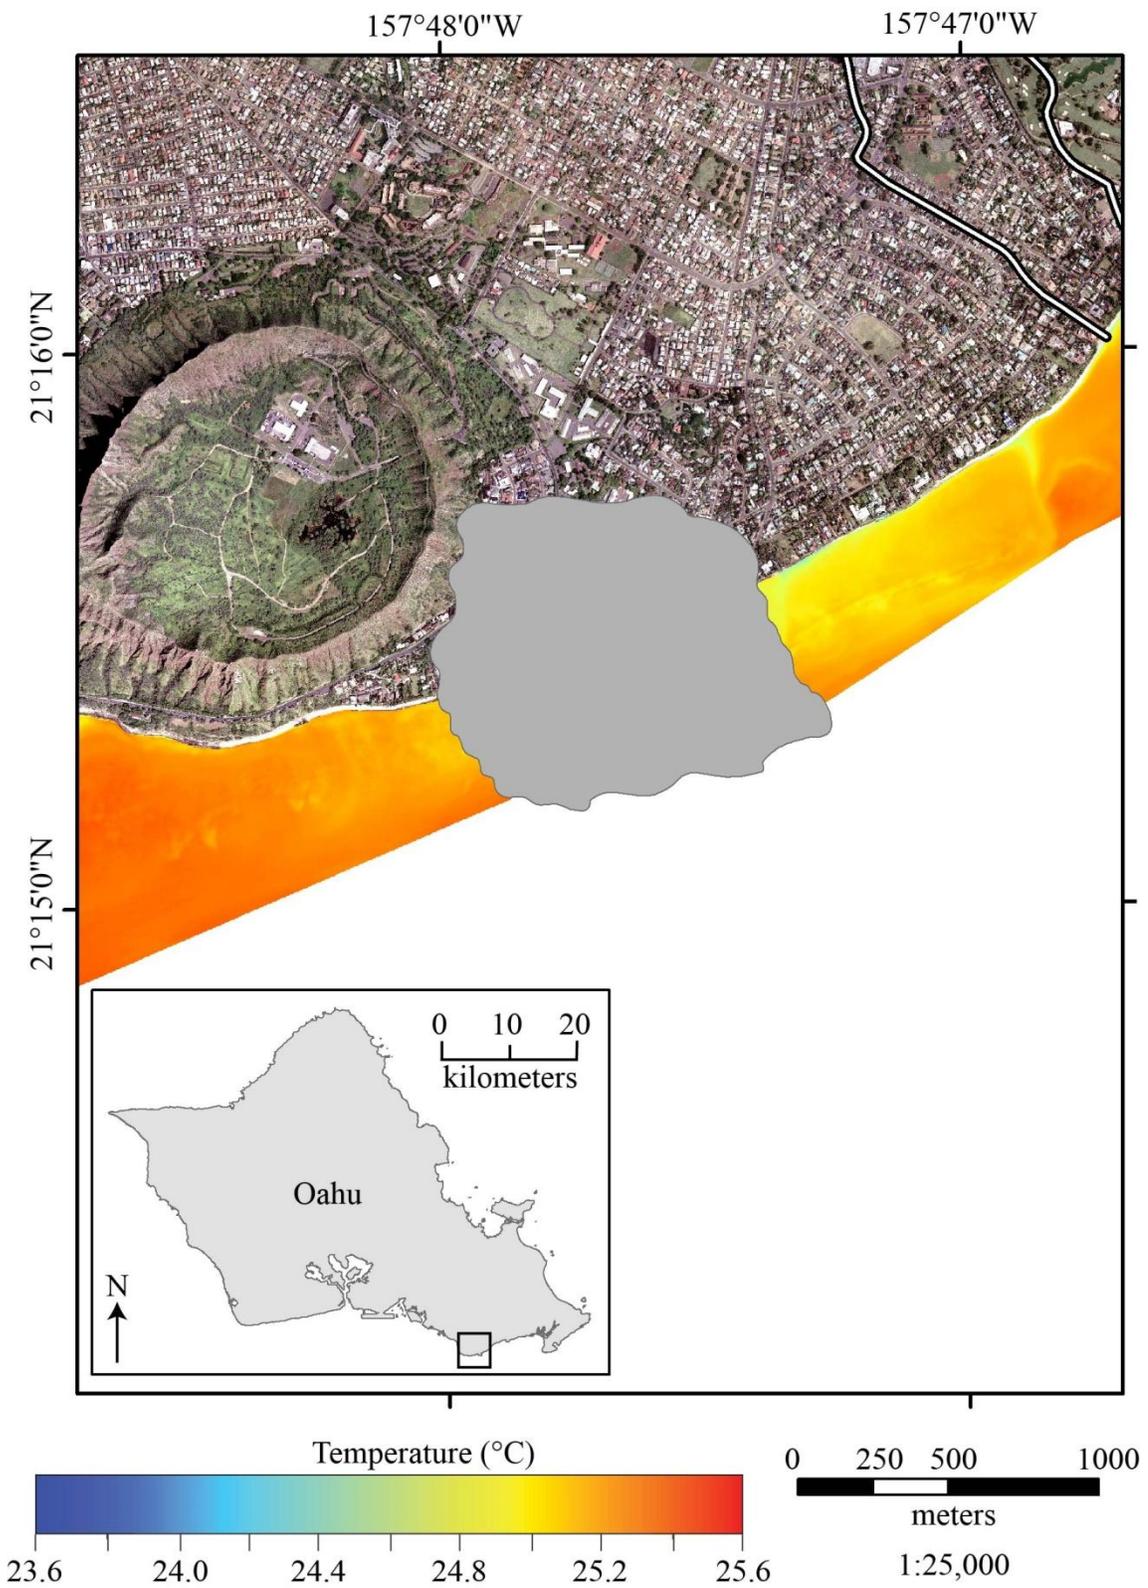

Panel 2: Hawaii Kai from 22 July 2009 at 01:31-01:56 a.m., HST. Honolulu tide was +0.12-0.15 m.

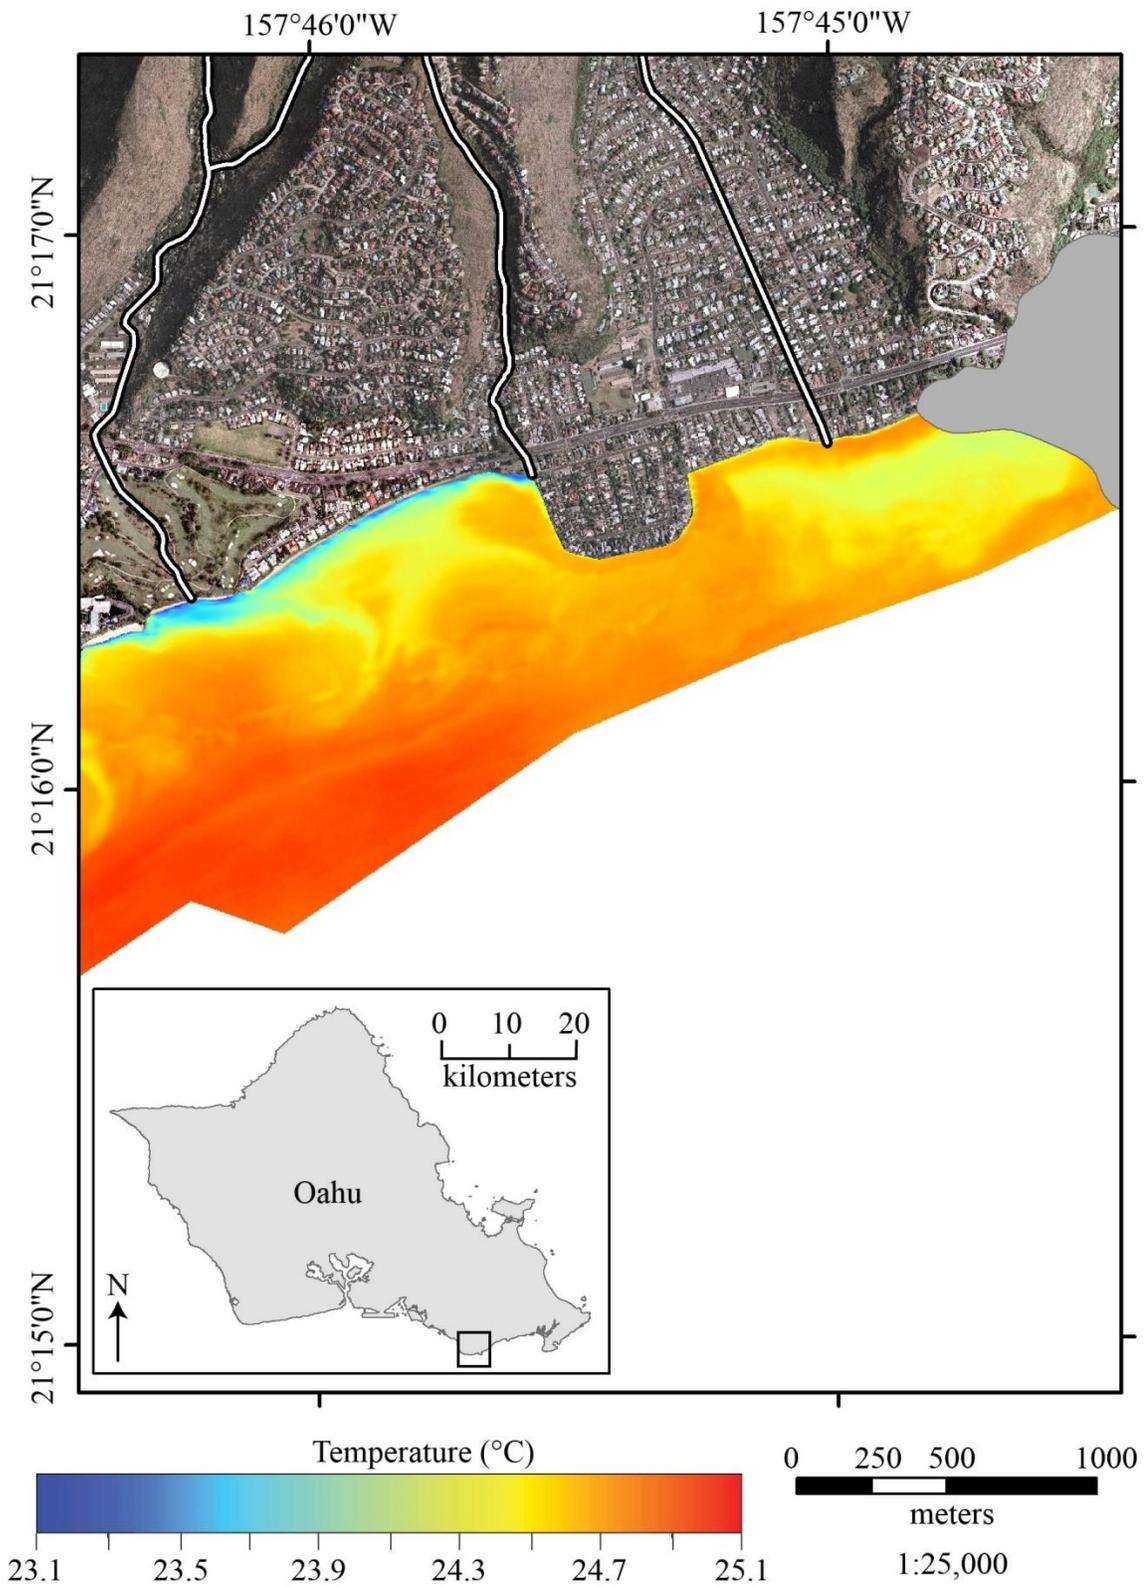

Panel 3: Niu Peninsula and Paiko Lagoon from 6 July 2009 at 02:04-02:09 a.m., HST. Honolulu tide was +0.16 m MLLW.

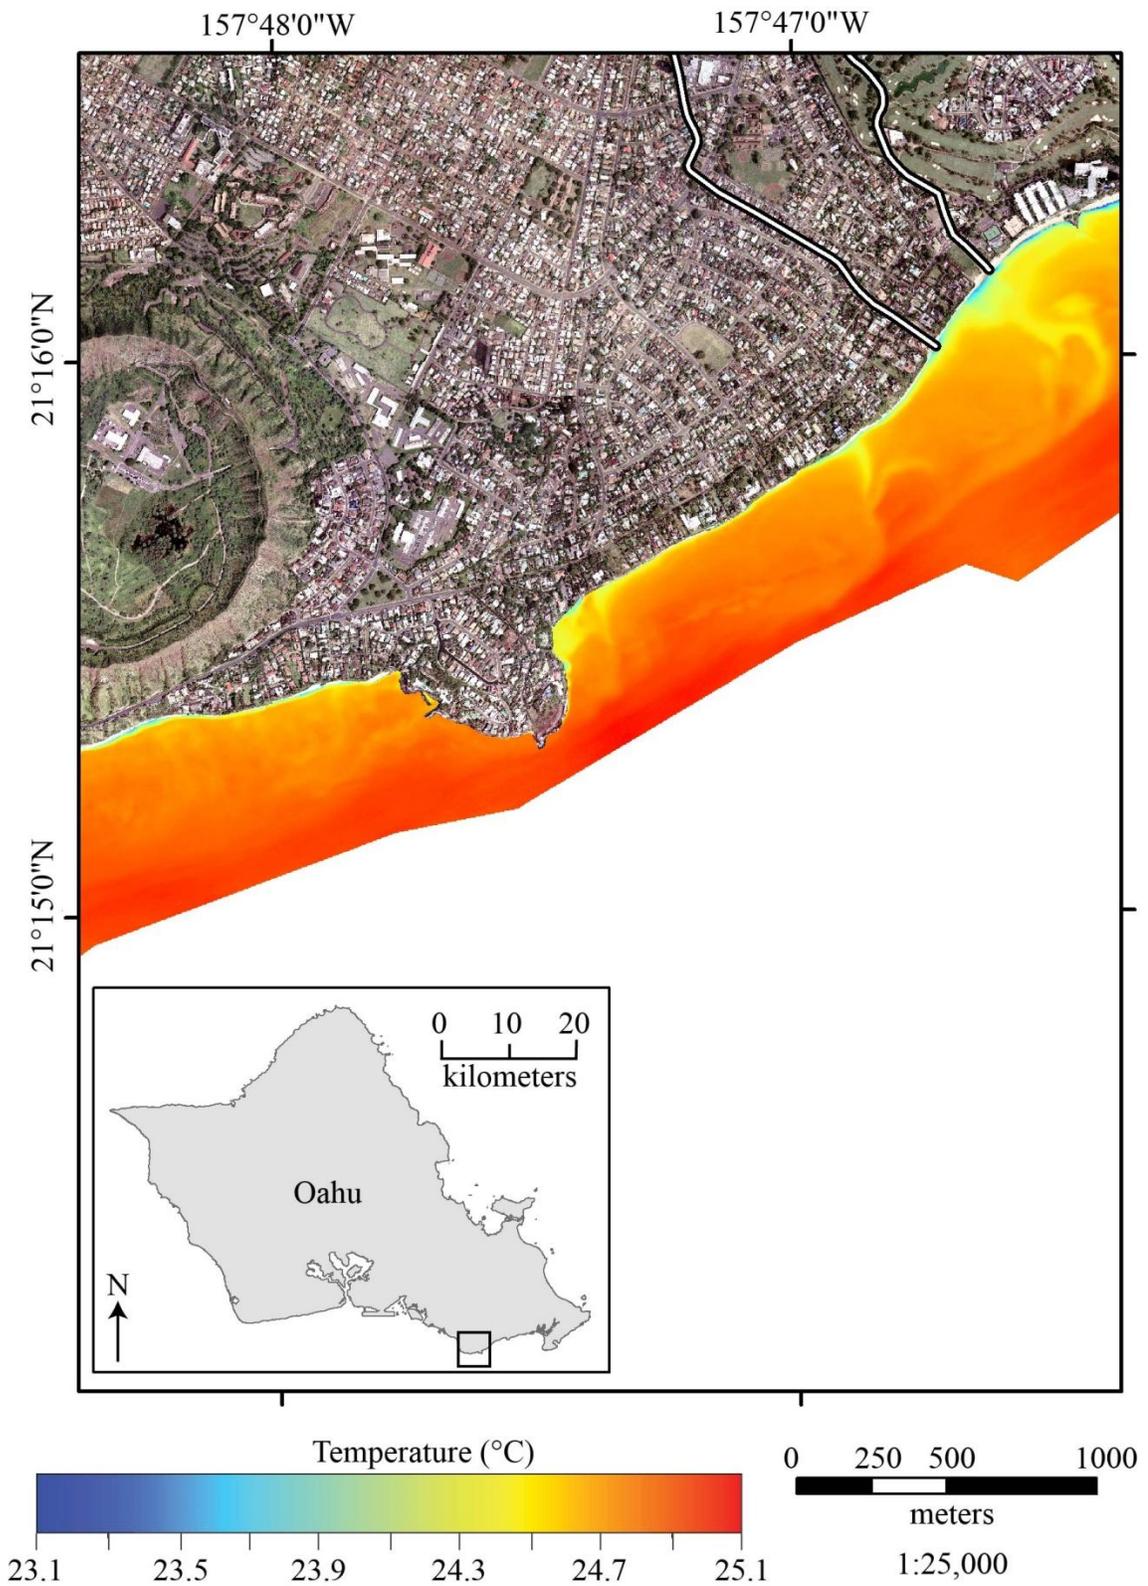

Panel 4: Wailupe Beach Park from 6 July 2009 at 02:04-02:09 a.m., HST. Honolulu tide was +0.16m MLLW.

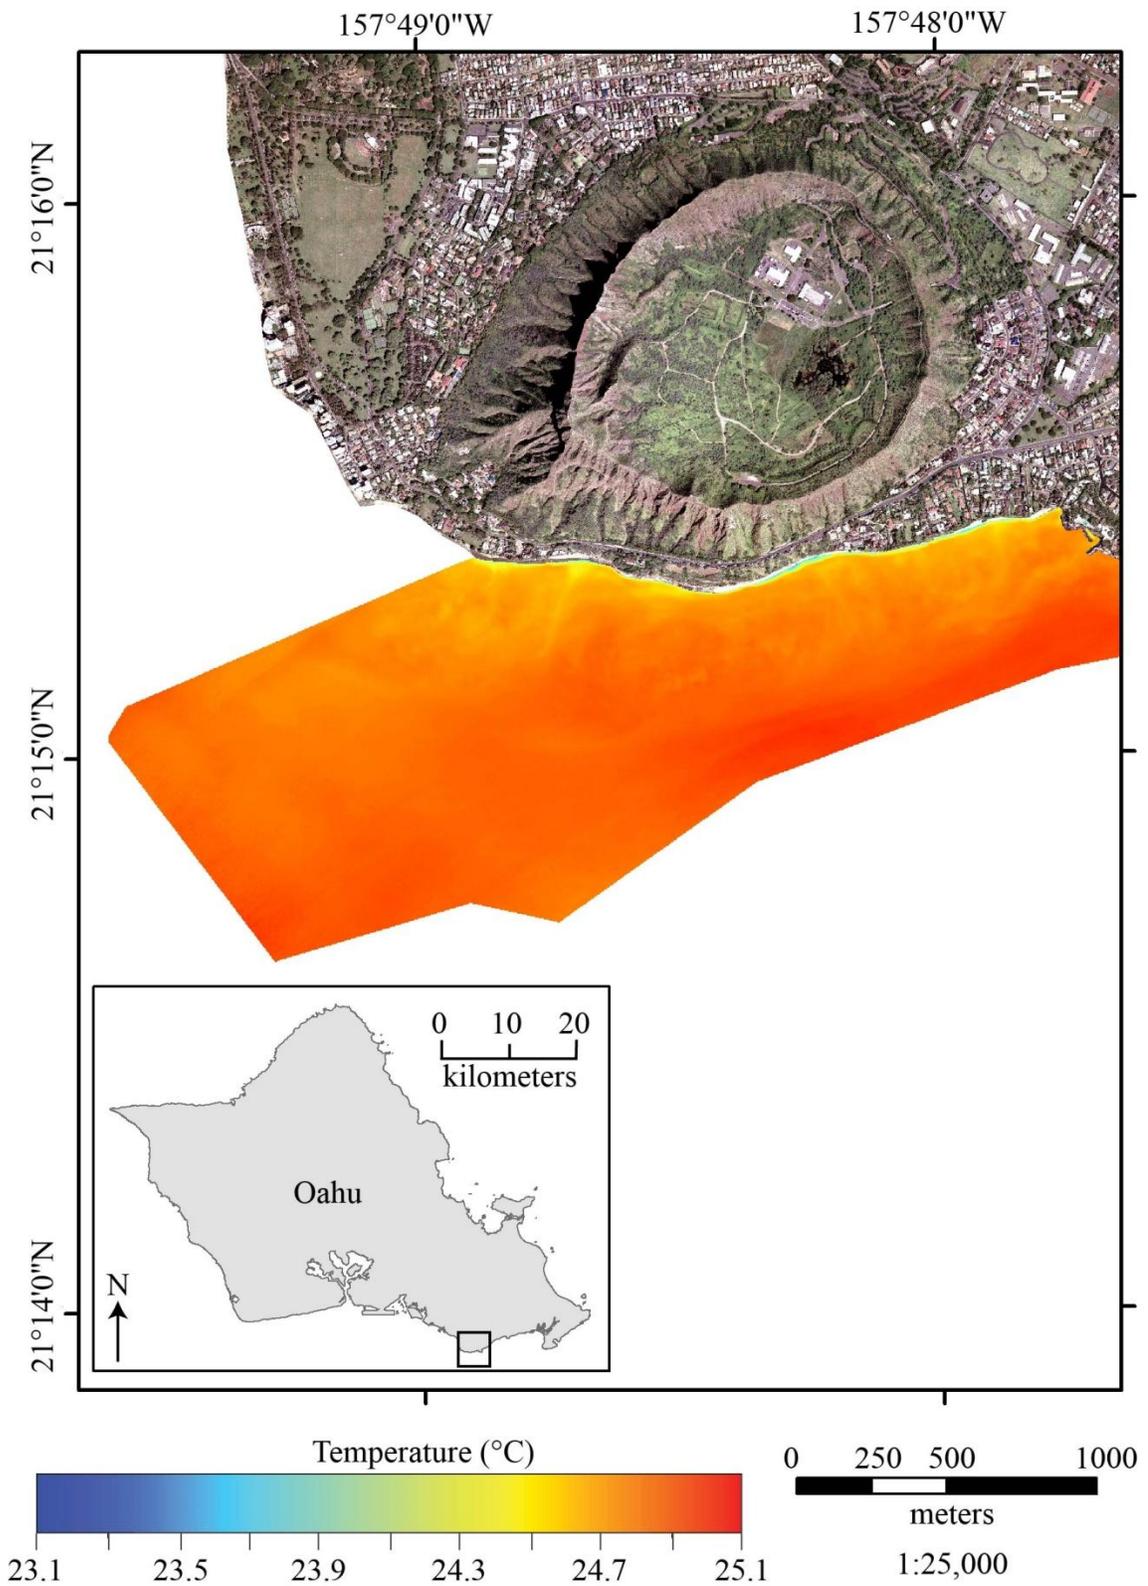

Panel 5: Diamond Head from 6 July 2009 at 02:04-02:09 a.m., HST. Honolulu tide was +0.16 m MLLW.

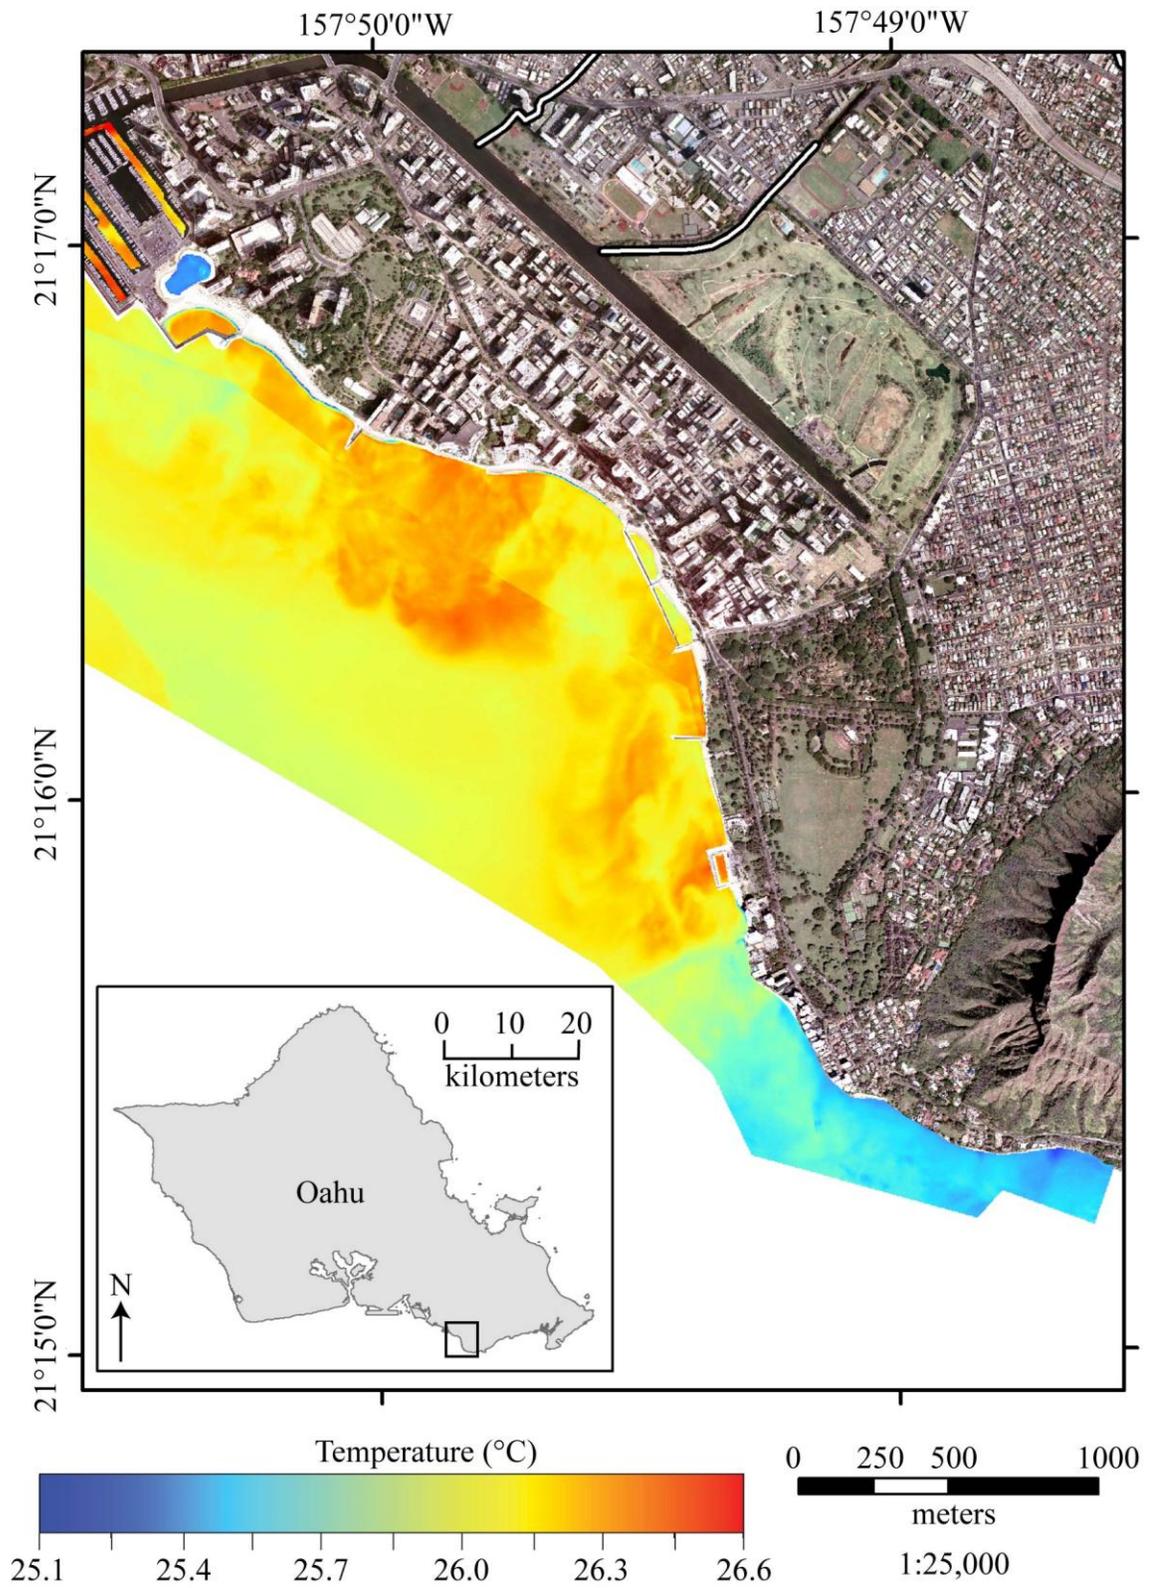

Panel 6: Niu Peninsula and Wailupe Beach Park from 22 July 2009 at 02:01-02:06 a.m., HST. Honolulu tide was +0.16 m MLLW.

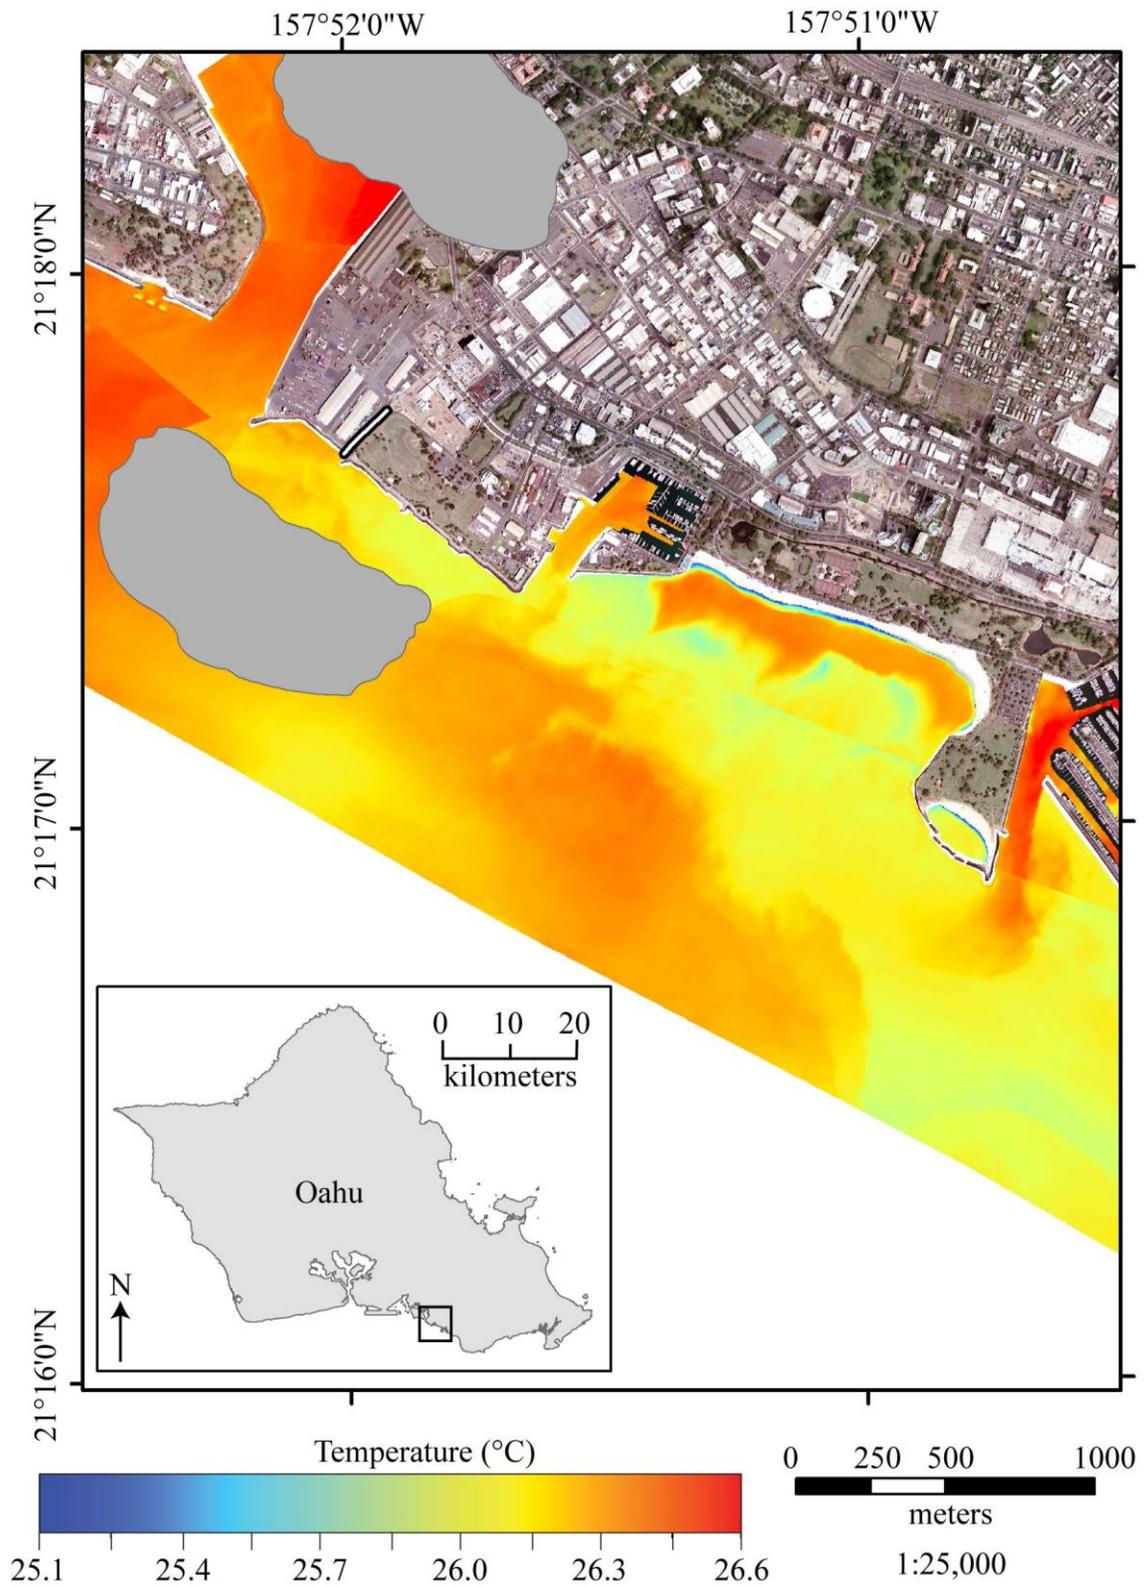

Panel 7: Black Point from 22 July 2009 at 02:01-02:06 a.m., HST. Honolulu tide was +0.16 m MLLW.

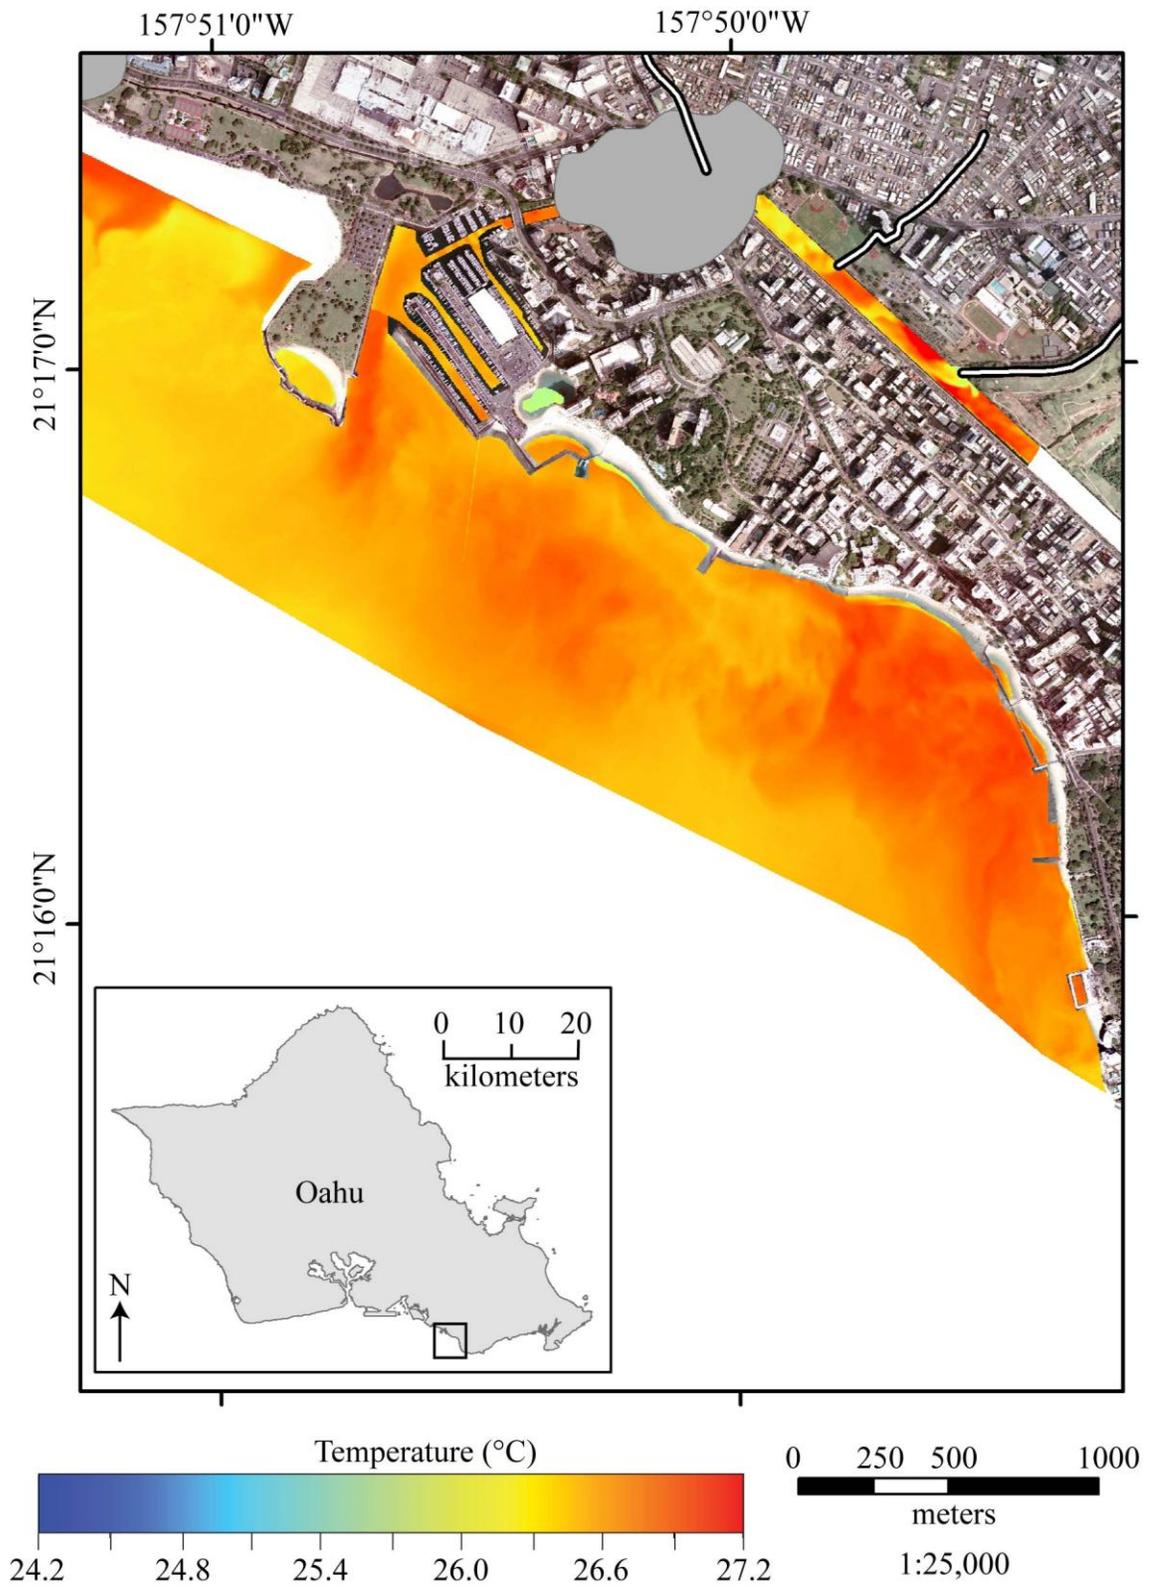

Panel 8: Diamond Head from 22 July 2009 at 02:01-02:06 a.m., HST. Honolulu tide was +0.16 m MLLW.

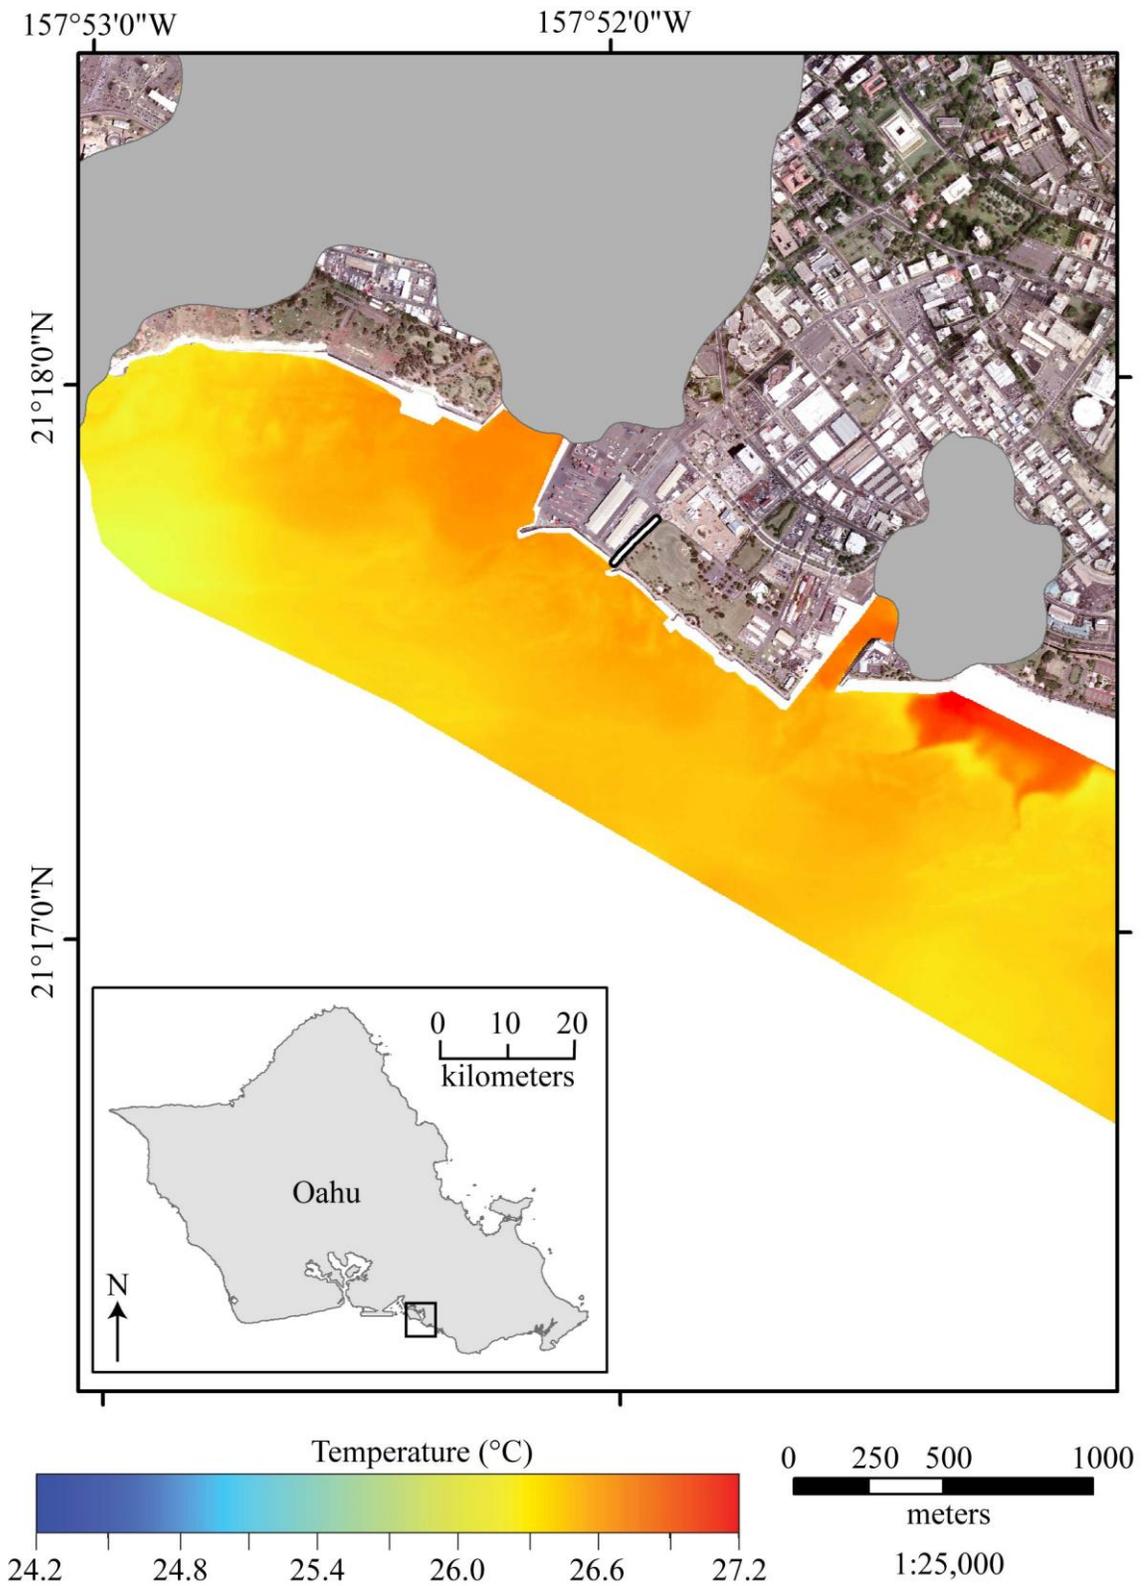

Panel 9: Diamond Head and Waikiki from 6 July 2009 at 01:12-01:54 a.m., HST. Honolulu tide was +0.13 to +0.16 m MLLW.

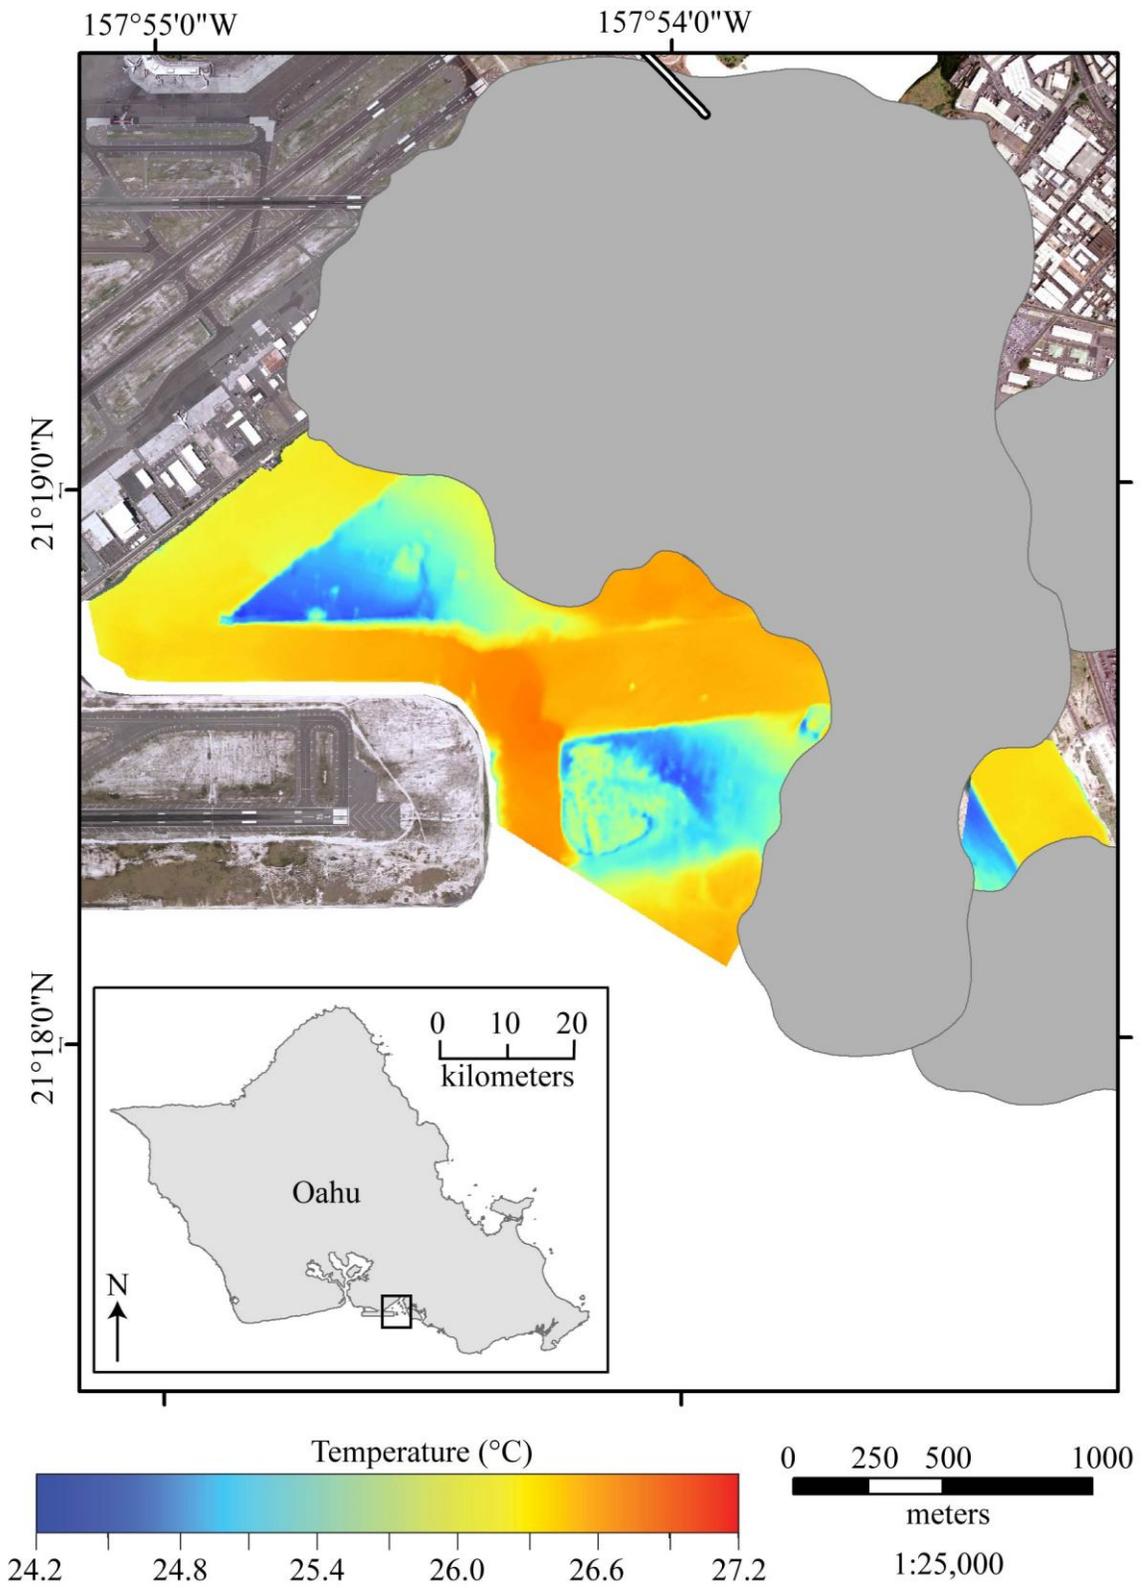

Panel 10: Ala Moana Regional Beach Park and Magic Island from 6 July 2009 at 01:12-01:54 a.m., HST. Honolulu tide was +0.13 to +0.16 m MLLW.

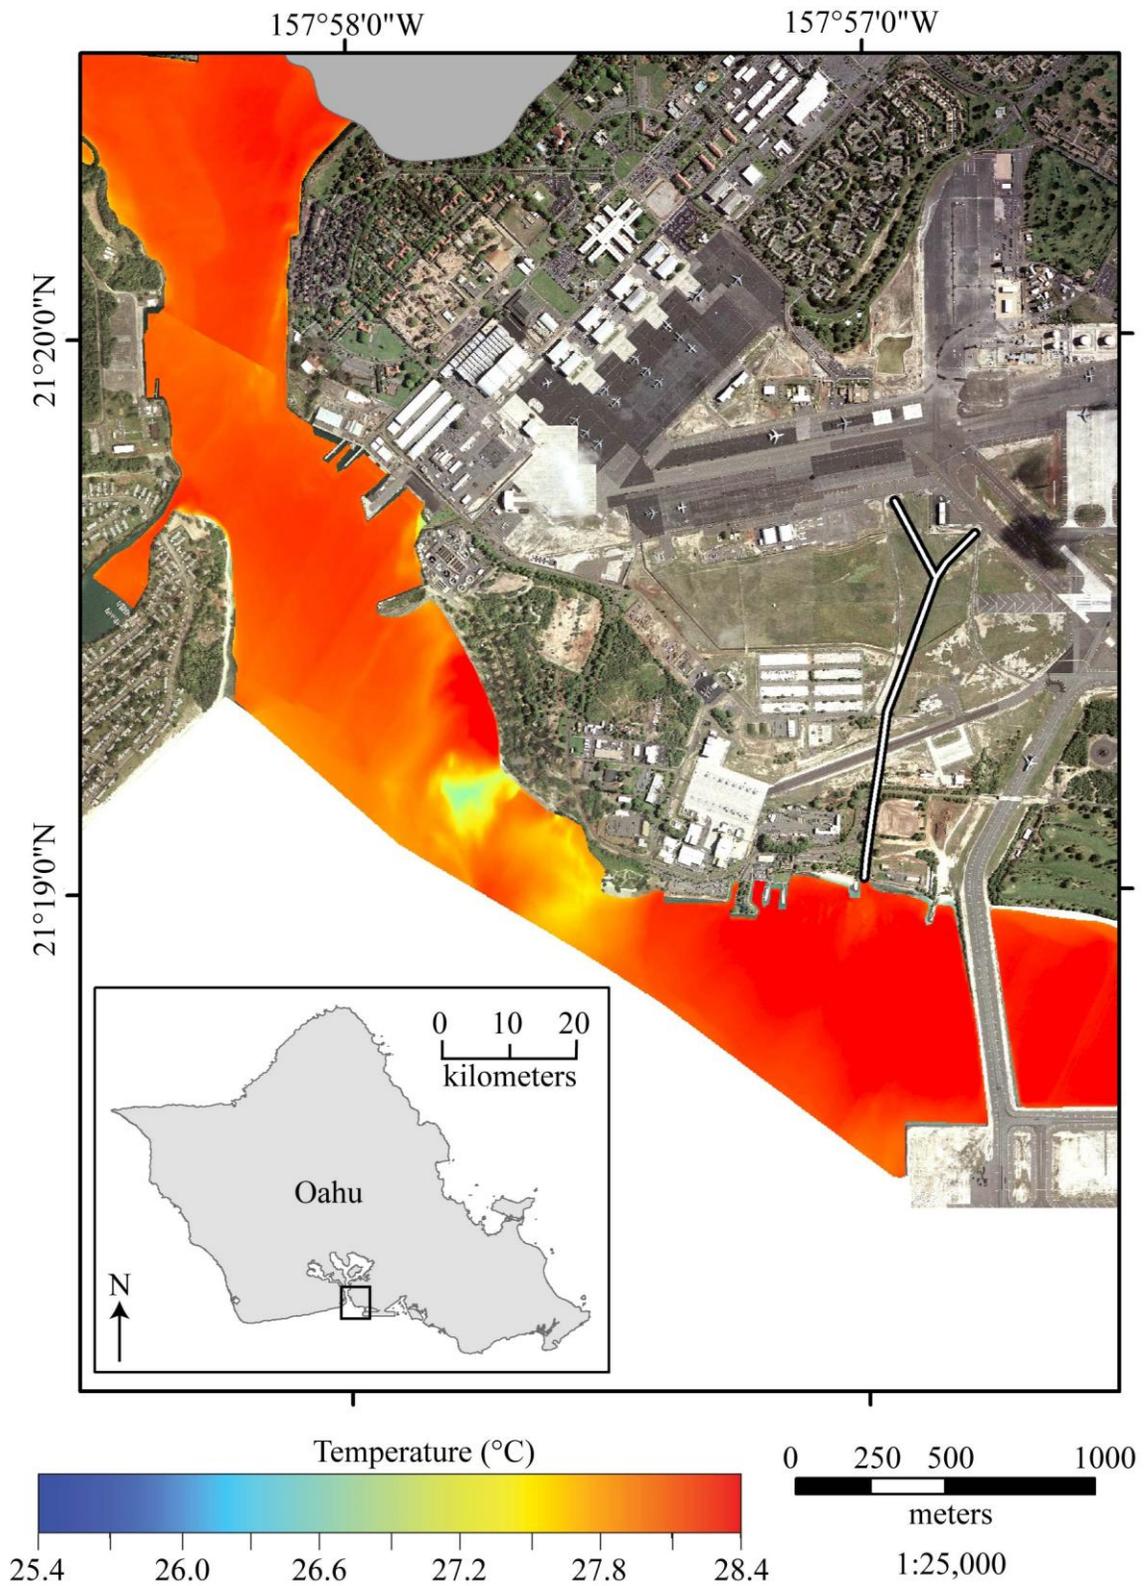

Panel 11: Waikiki and Ala Moana Regional Beach Park from 17 July 2009 at 02:14-02:51 a.m., HST. Honolulu tide was +0.04 to +0.08 m MLLW.

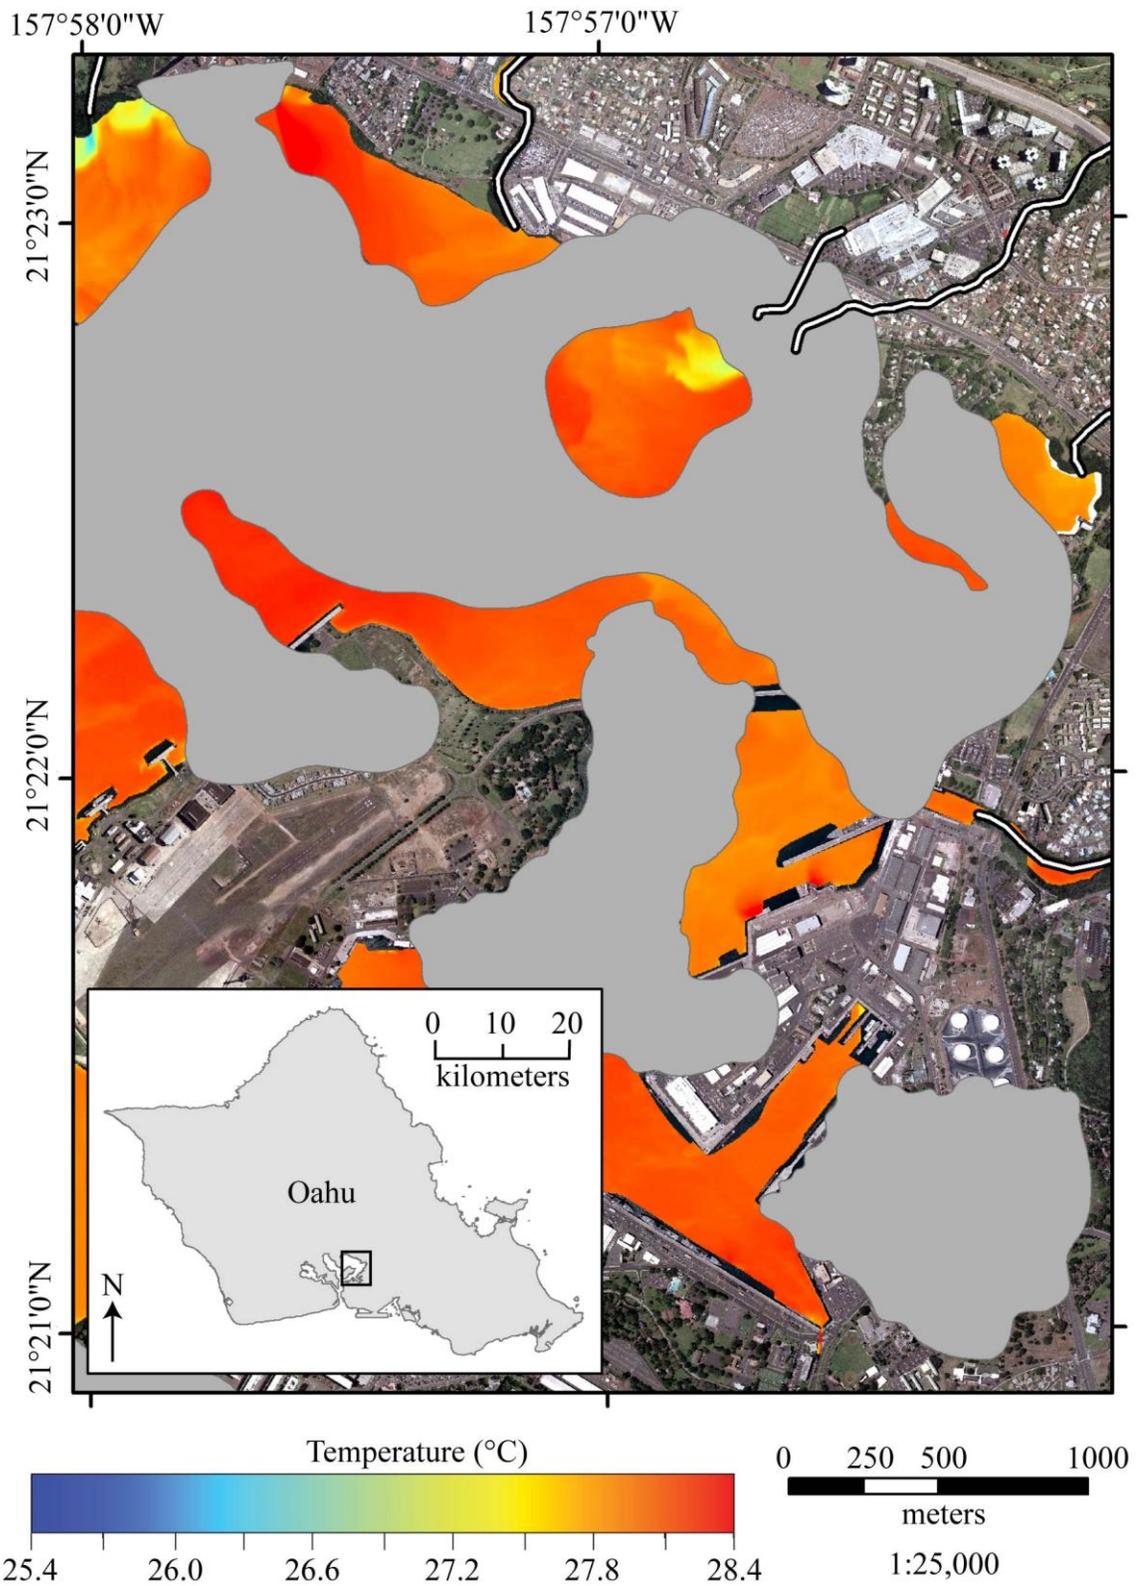

Panel 12: Ala Moana Regional Beach Park and Kakaako Waterfront Park from 17 July 2009 at 02:14-02:51 a.m., HST. Honolulu tide was +0.04 to +0.08 m MLLW.

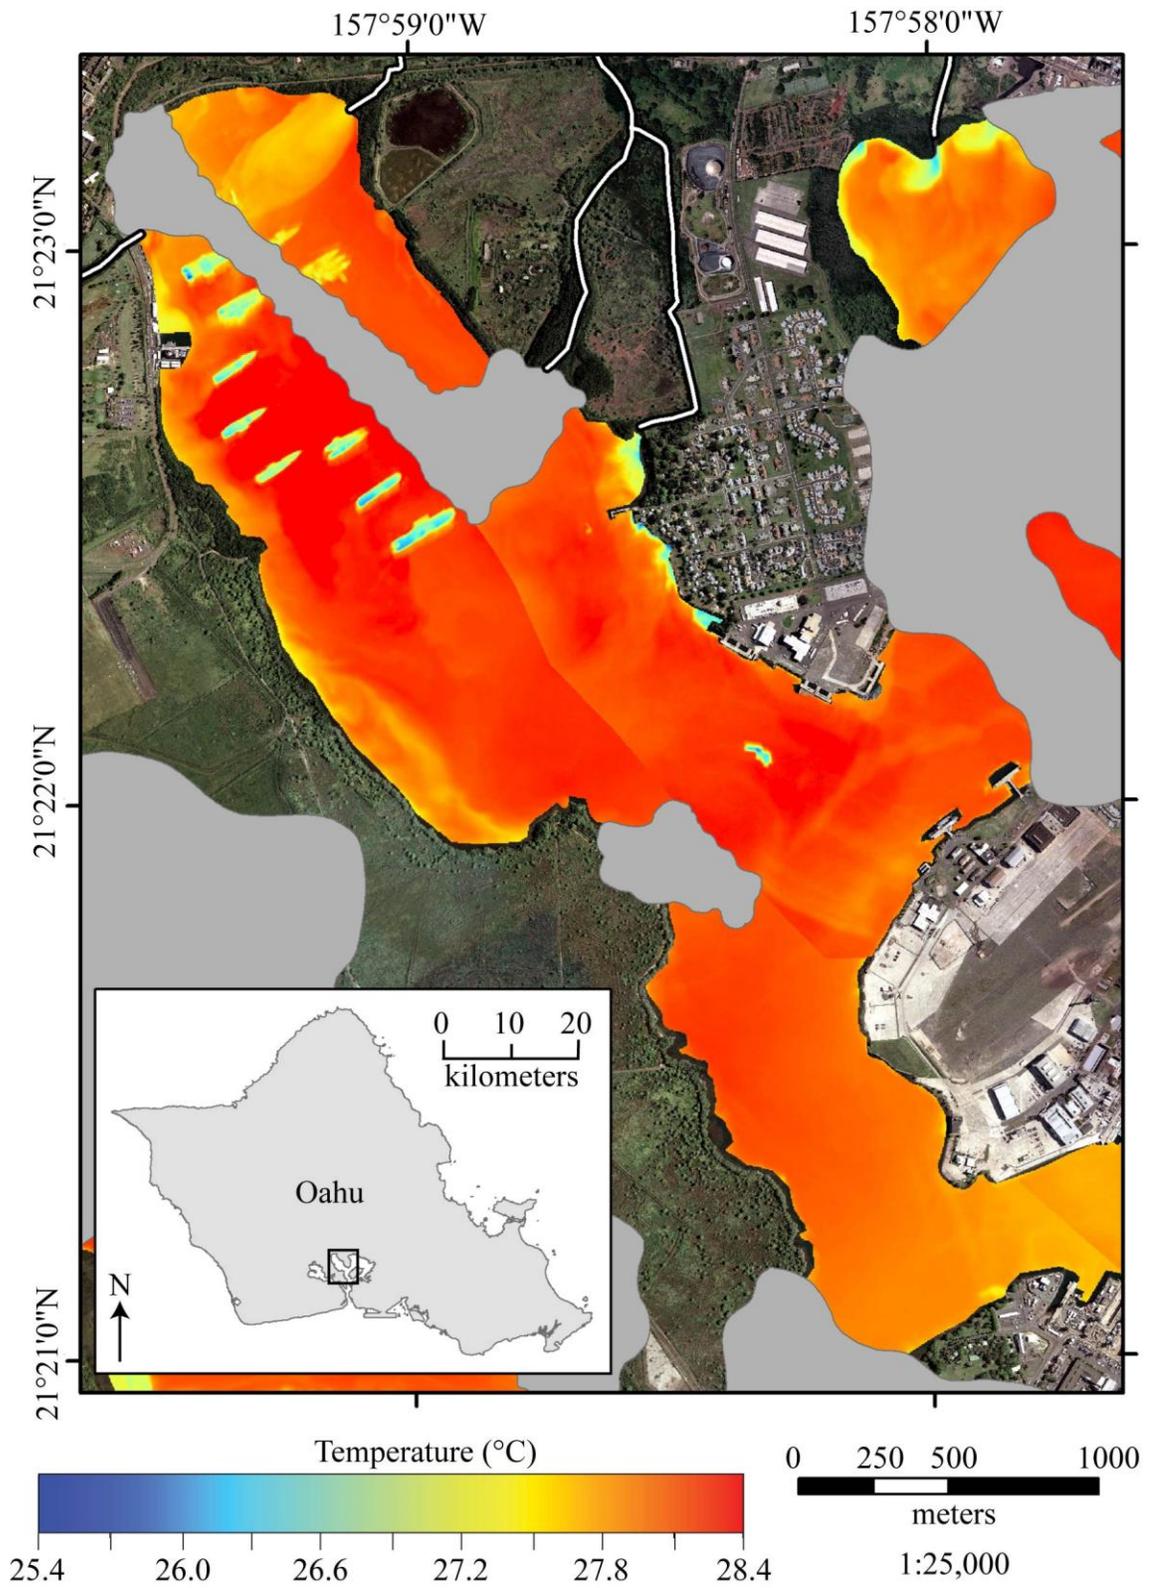

Panel 13: Reef runway from 17 July 2009 at 02:14-02:51 a.m., HST. Honolulu tide was +0.04 to +0.08 m MLLW.

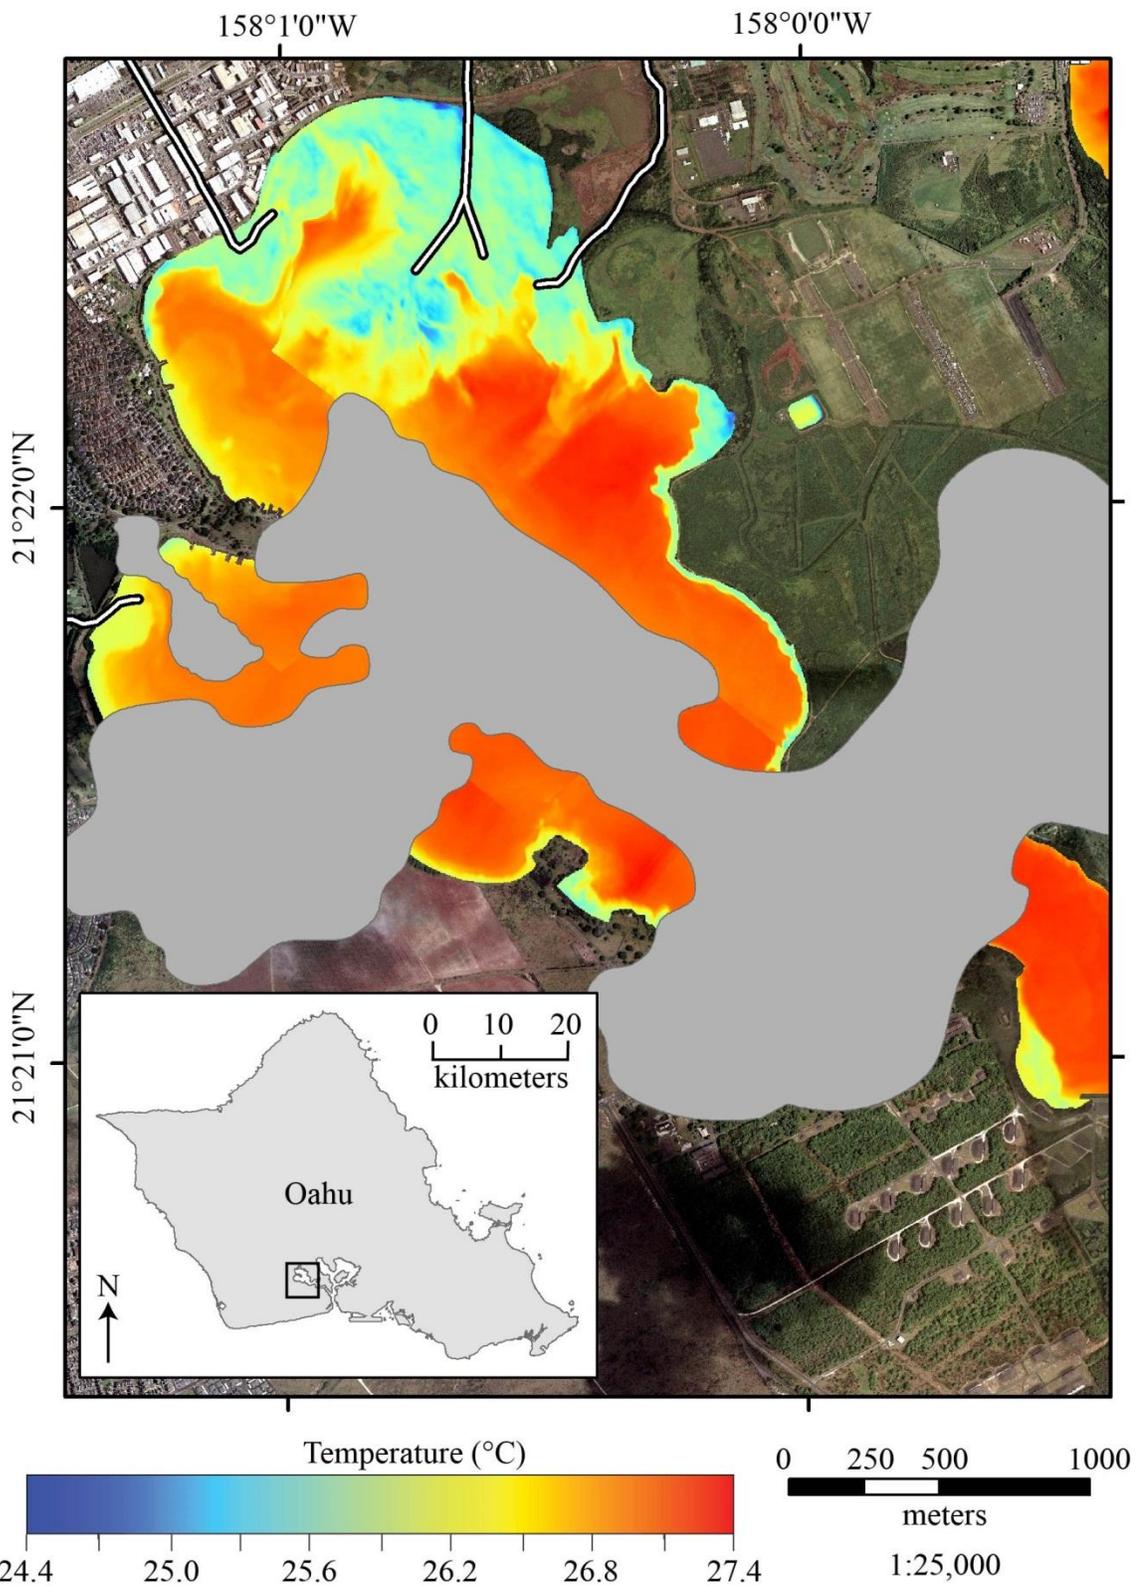

Panel 14: Mouth of Pearl Harbor from 17 July 2009 at 01:00-04:36 a.m., HST. Honolulu tide was -0.04 to +0.15 m MLLW.

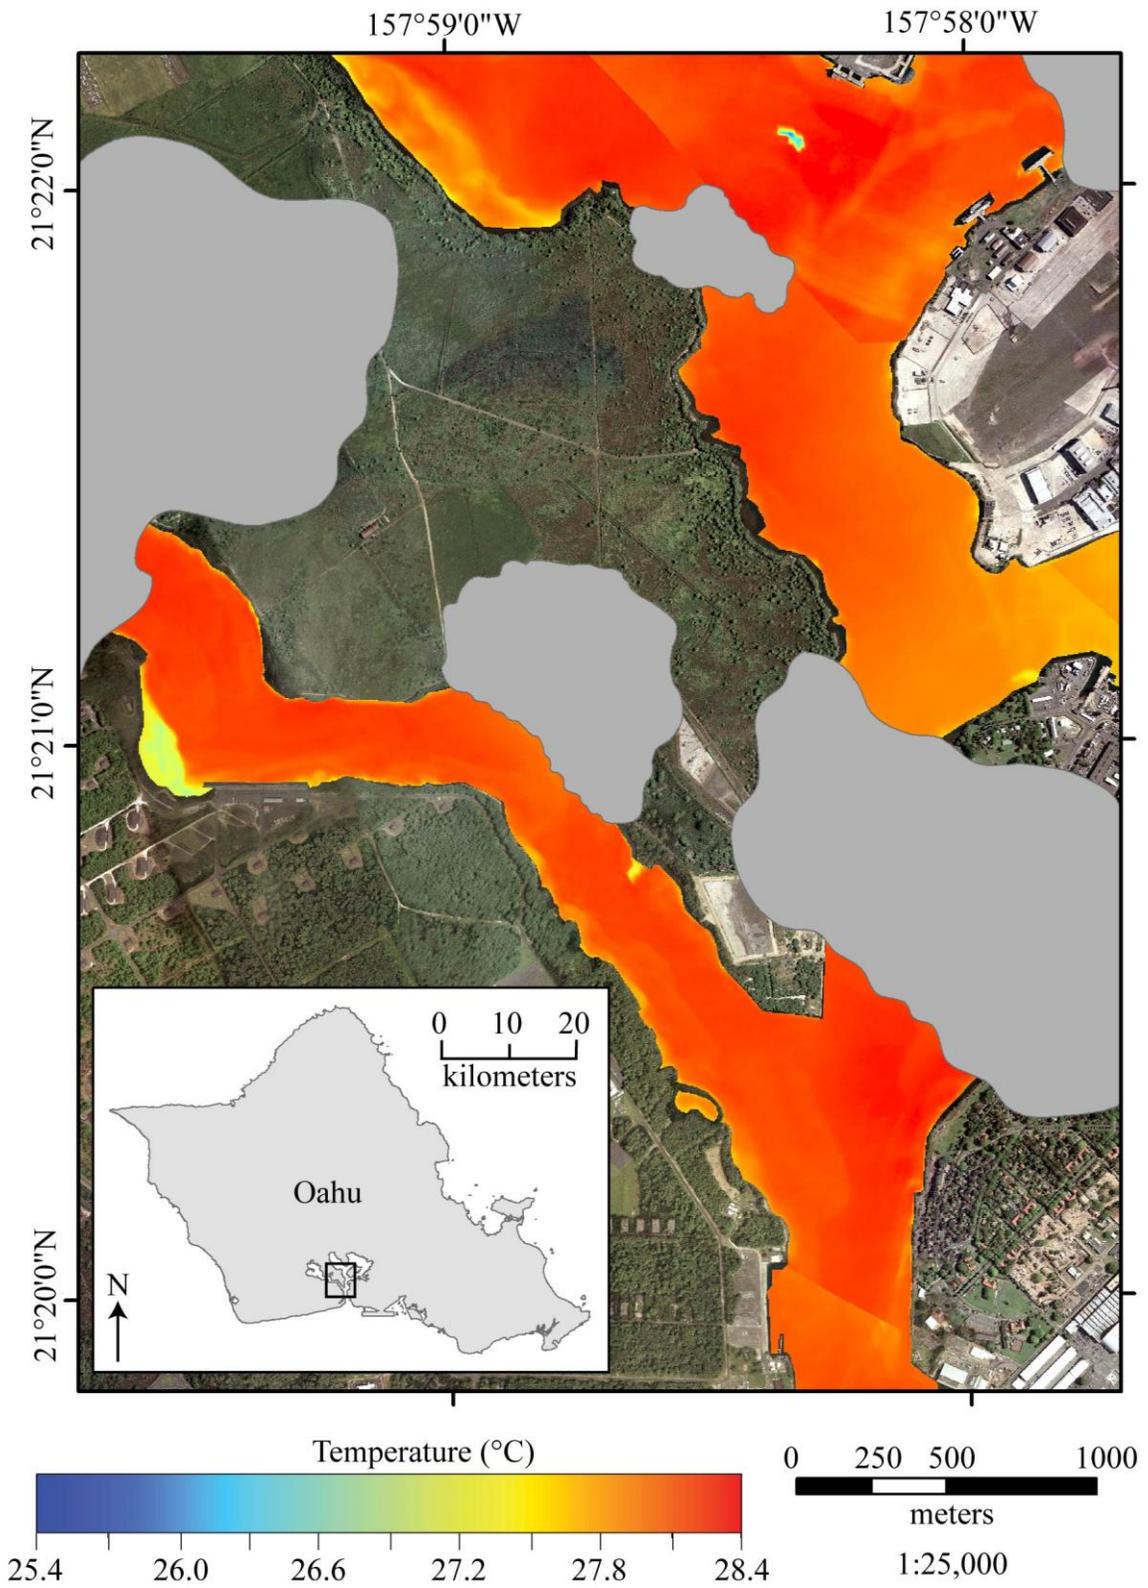

Panel 15: East Loch of Pearl Harbor from 17 July 2009 at 01:00-04:36 a.m., HST. Honolulu tide was -0.04 to +0.15 m MLLW.

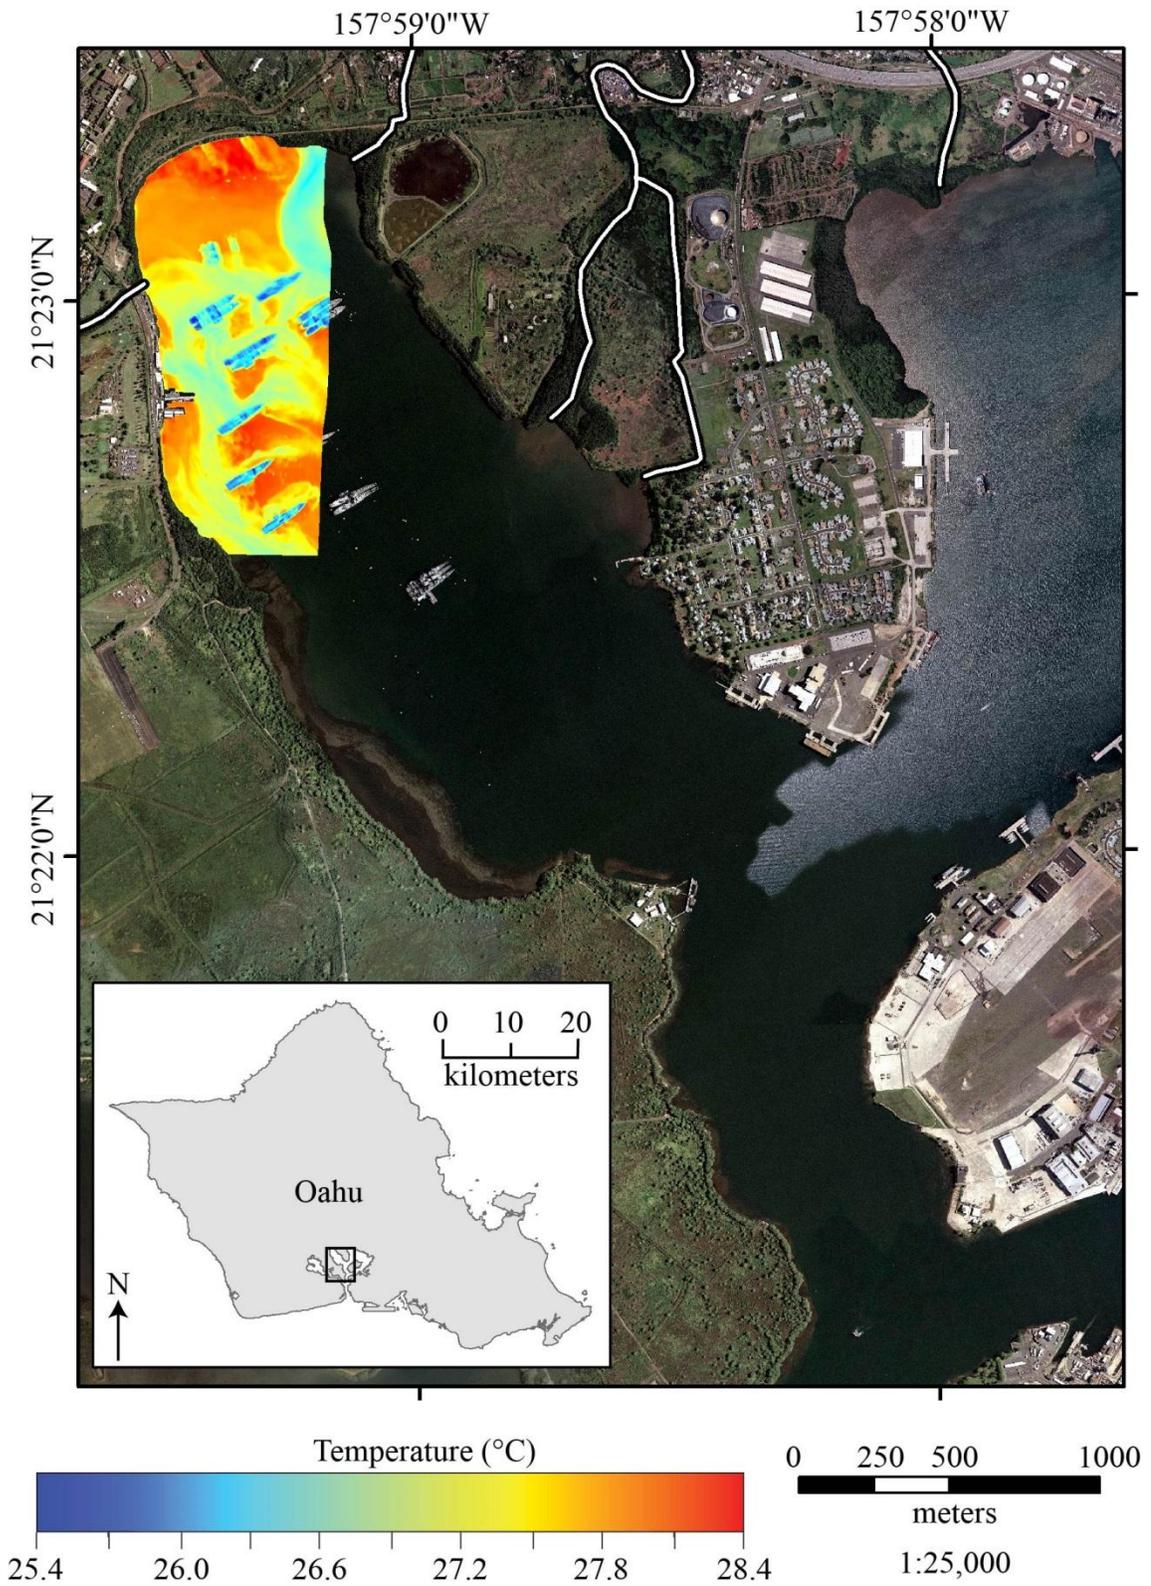

Panel 16: Middle Loch of Pearl Harbor from 17 July 2009 at 01:00-04:36 a.m., HST. Honolulu tide was -0.04 to +0.15 m MLLW.

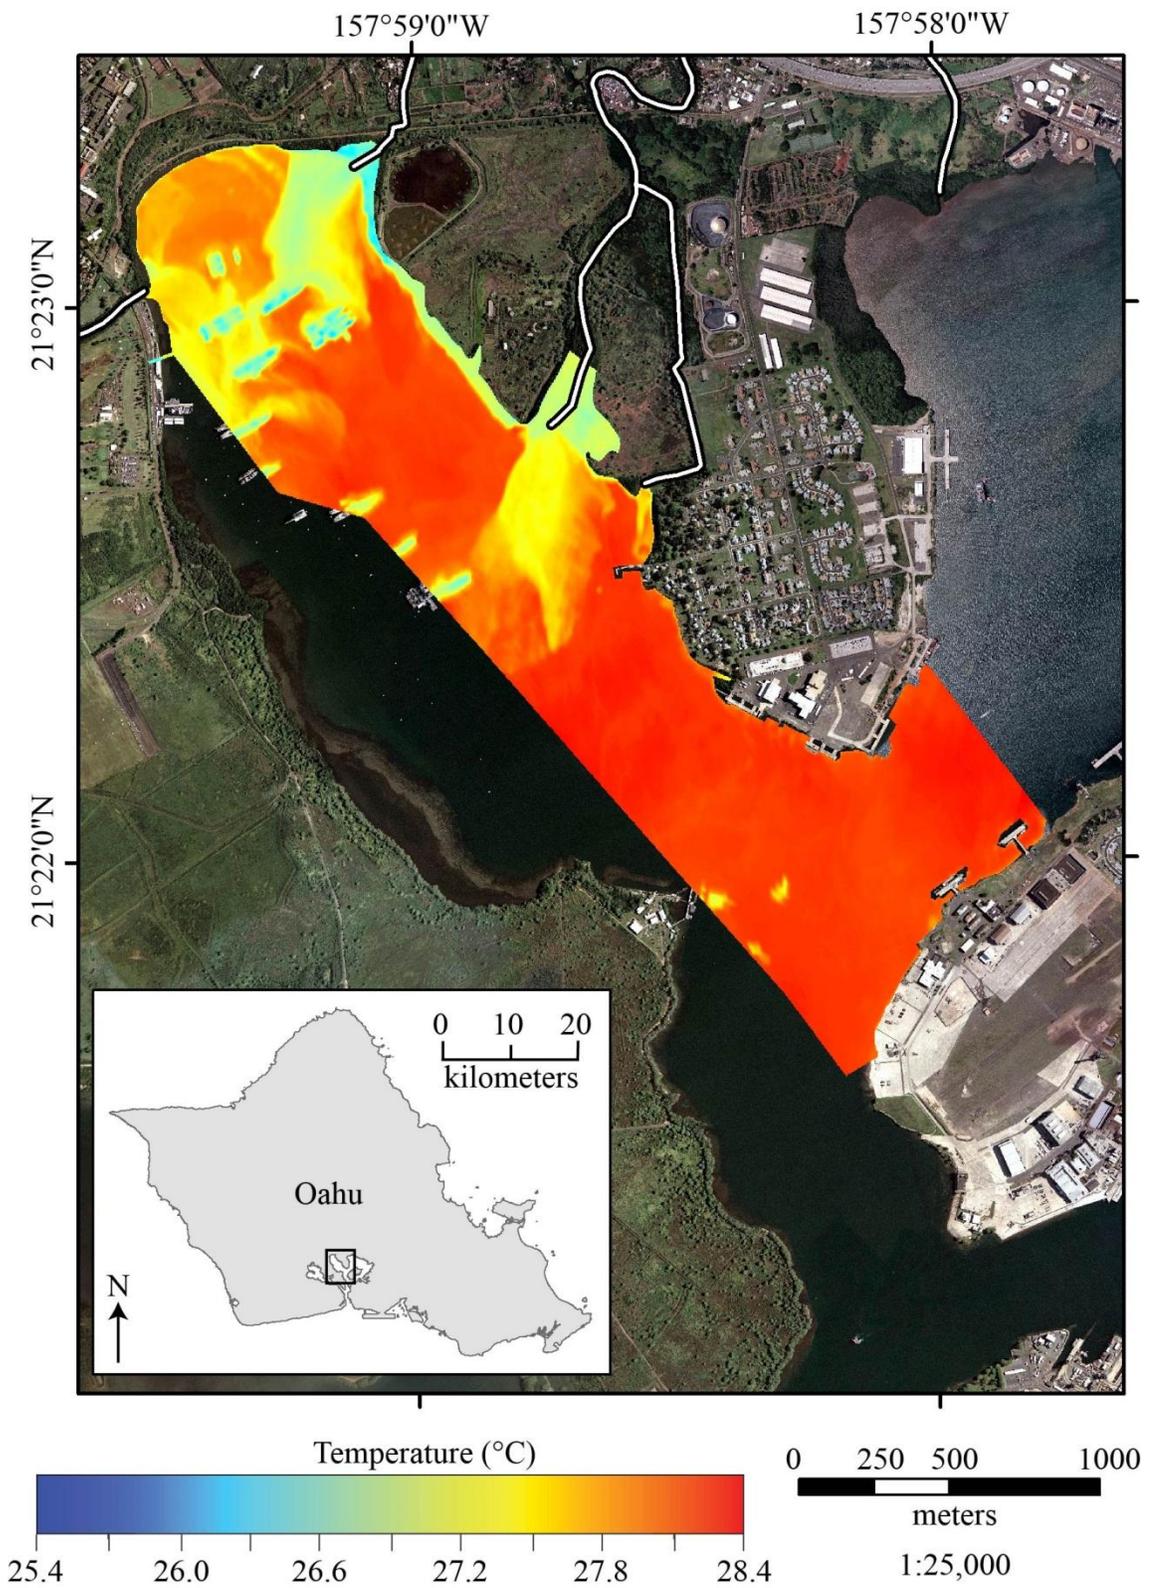

Panel 17: West Loch of Pearl Harbor from 17 July 2009 at 01:00-04:36 a.m., HST. Honolulu tide was -0.04 to +0.15 m MLLW.

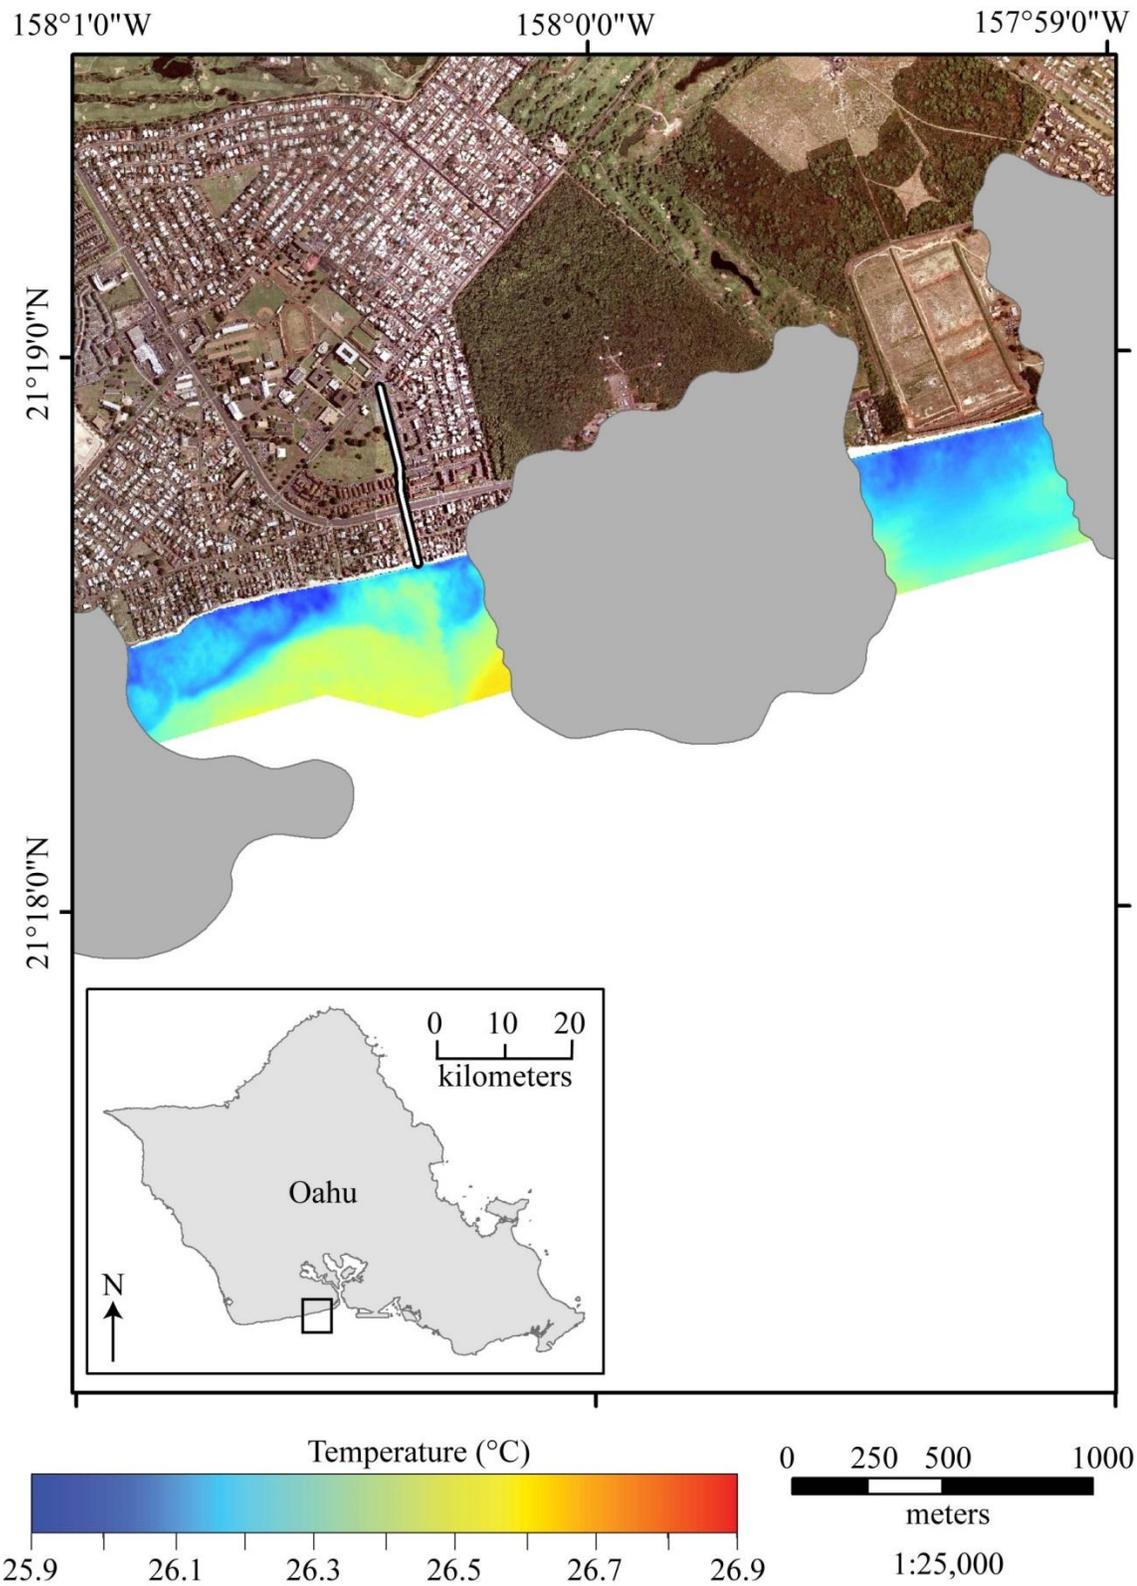

Panel 18: Channel of West Loch, Pearl Harbor from 17 July 2009 at 01:00-04:36 a.m., HST. Honolulu tide was -0.04 to +0.15 m MLLW.

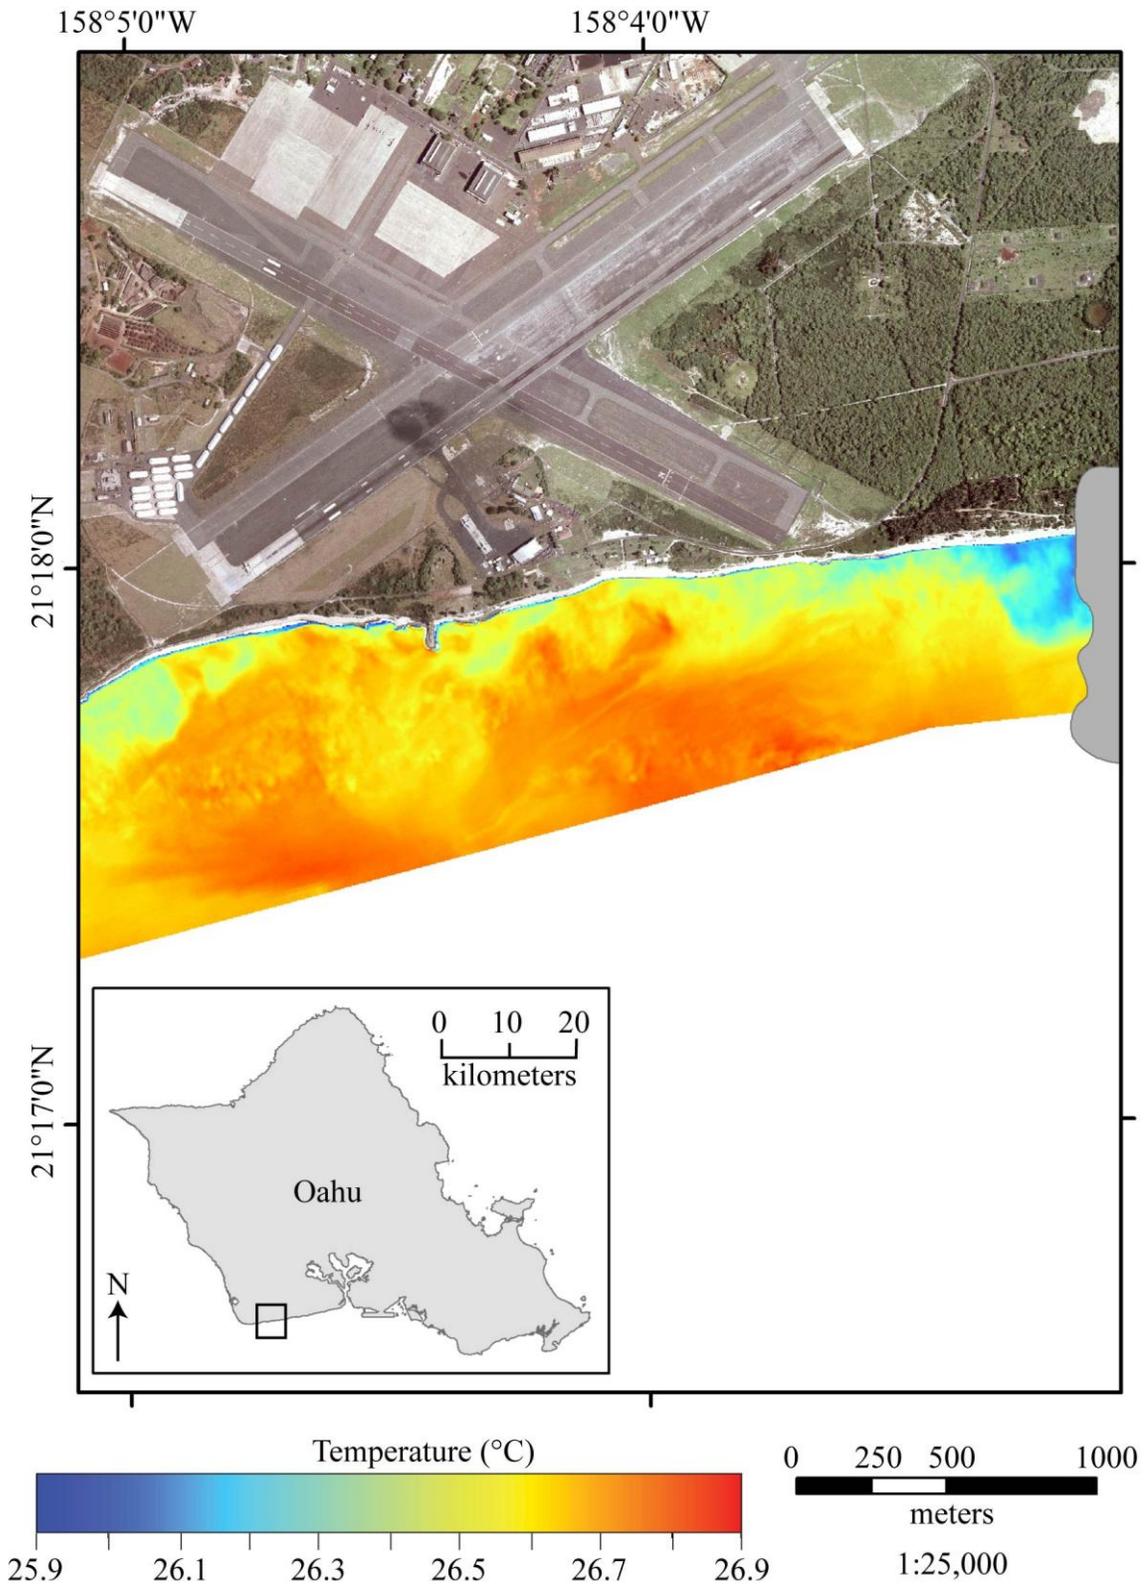

Panel 19: Middle Loch, Pearl Harbor from 12 June 2009 at 06:27-06:28 a.m., HST. Honolulu tide was +0.16 m MLLW.

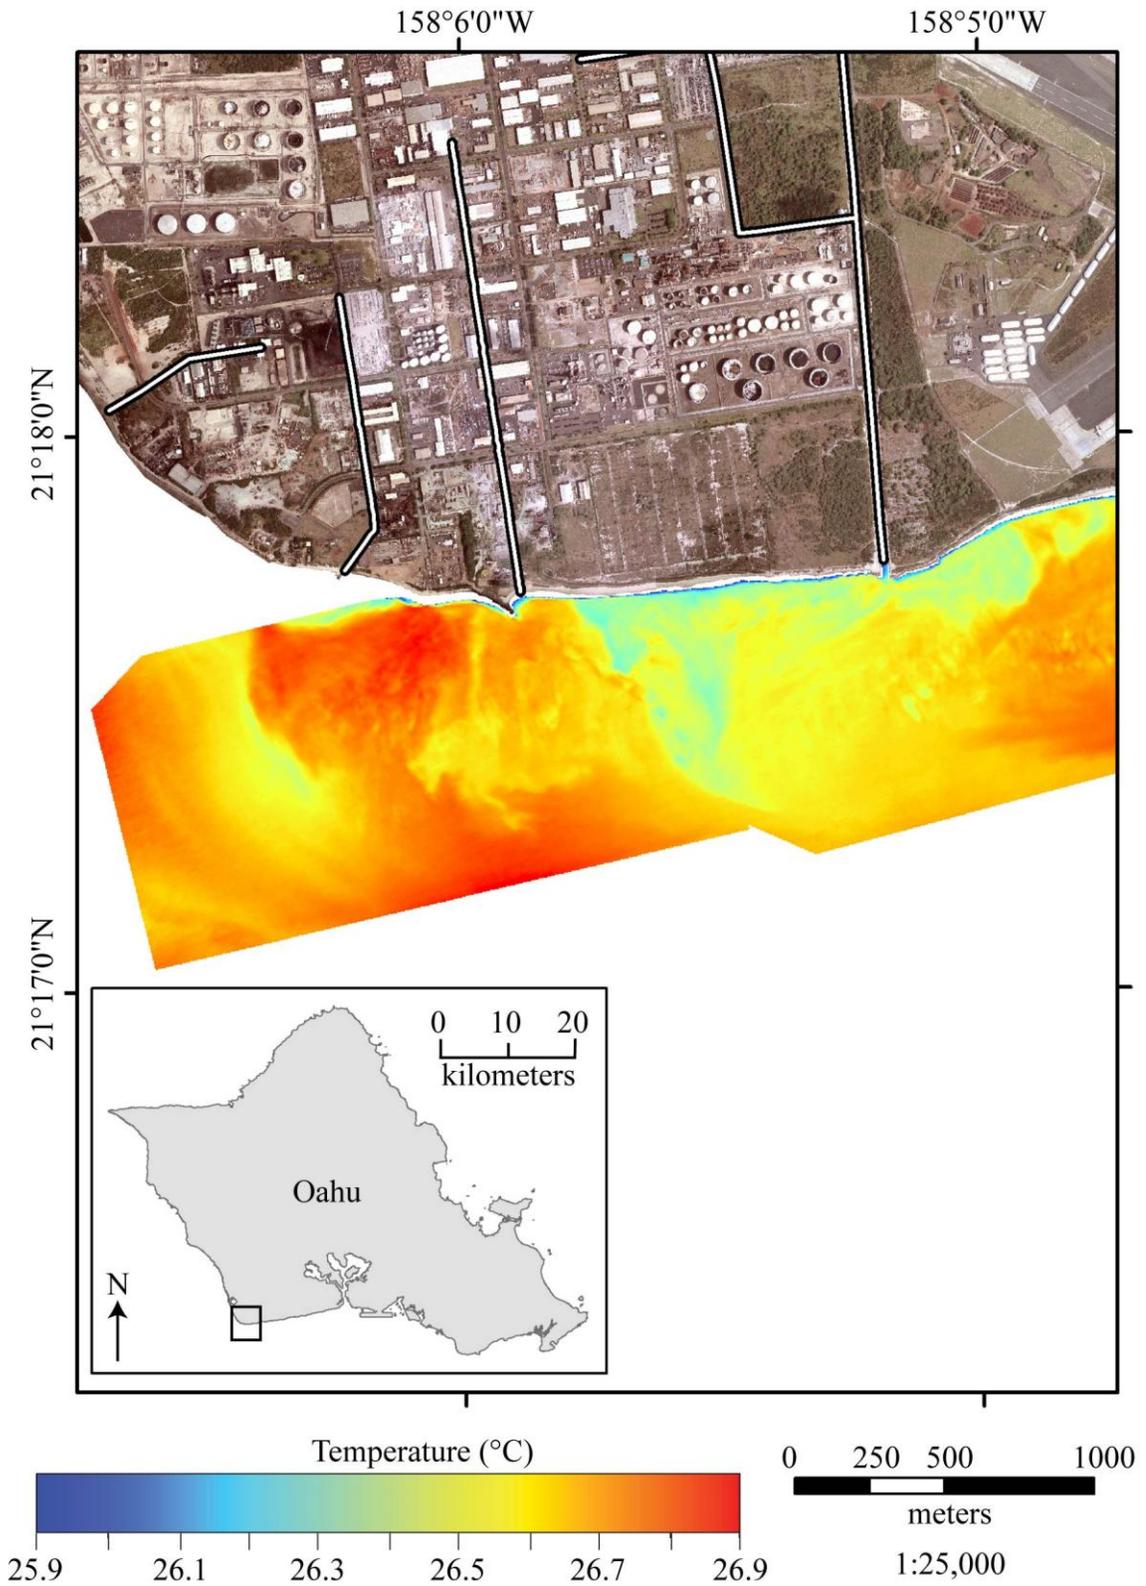

Panel 20: Middle Loch, Pearl Harbor from 22 June 2009 at 02:34-02:36 a.m., HST. Honolulu tide was +0.20 m MLLW.

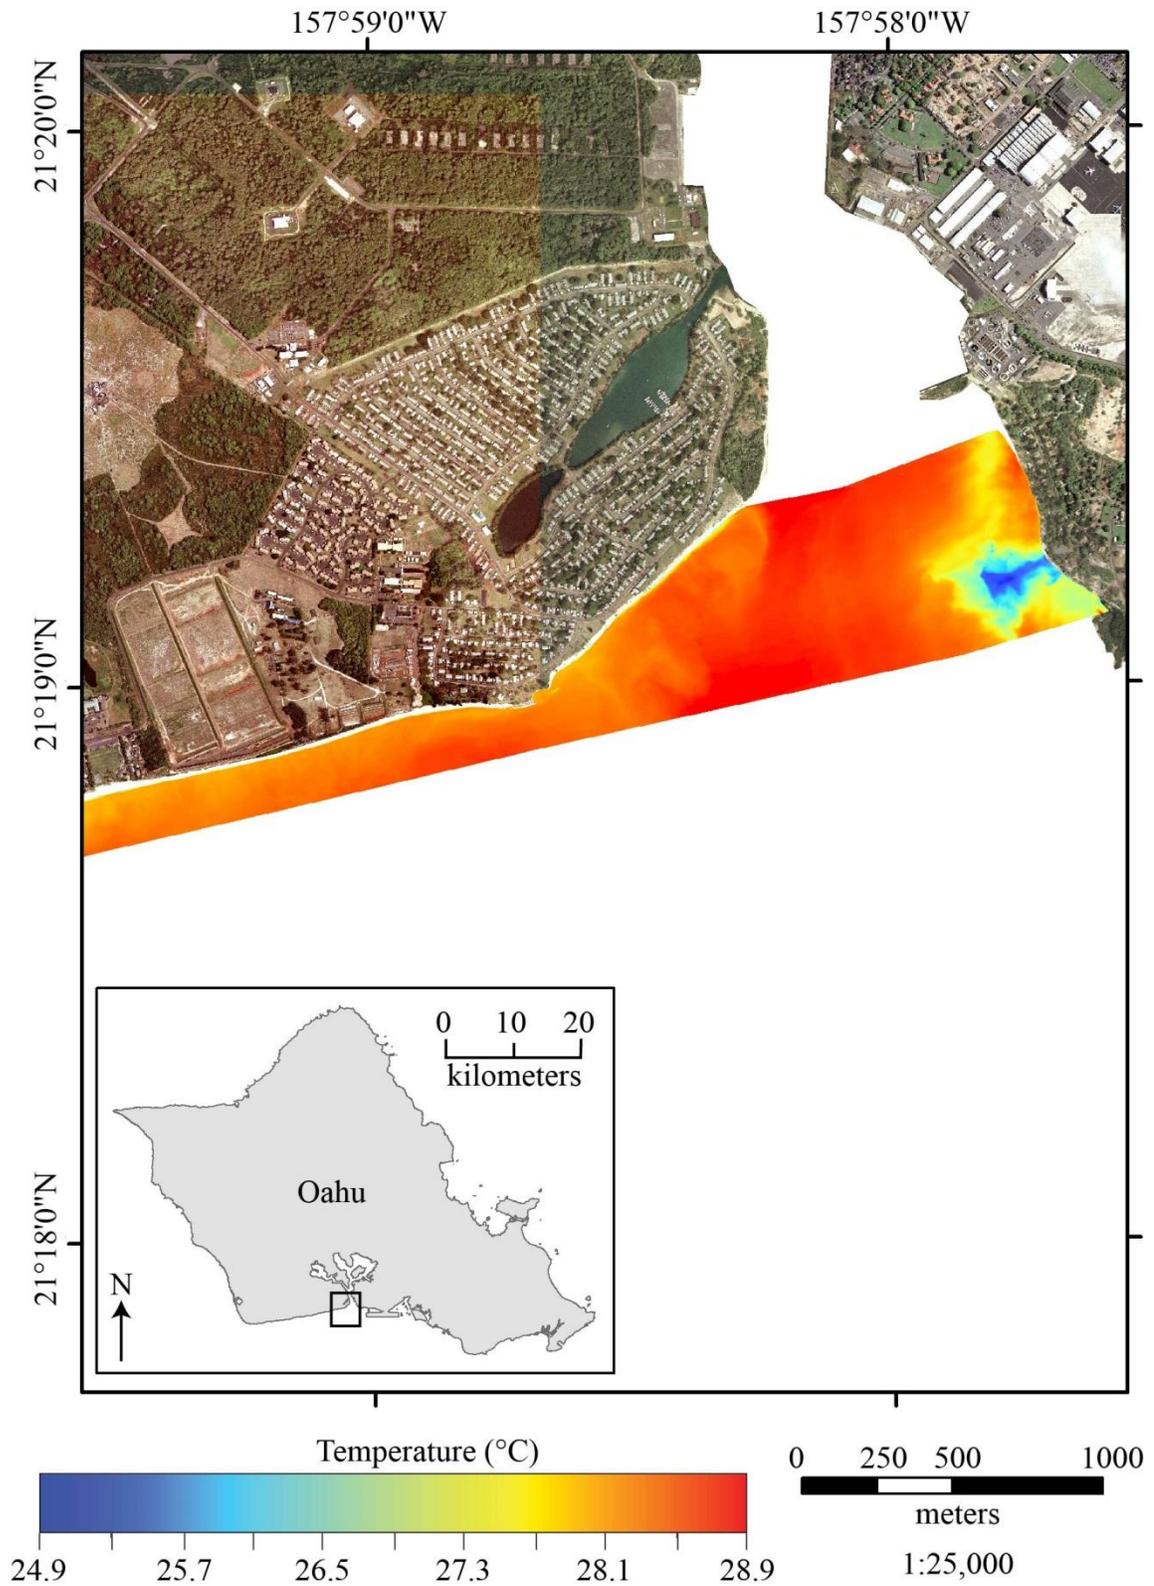

Panel 21: Ewa Beach from 6 July 2009 at 02:49-02:55 a.m., HST. Honolulu tide was +0.17 to +0.18 m MLLW.

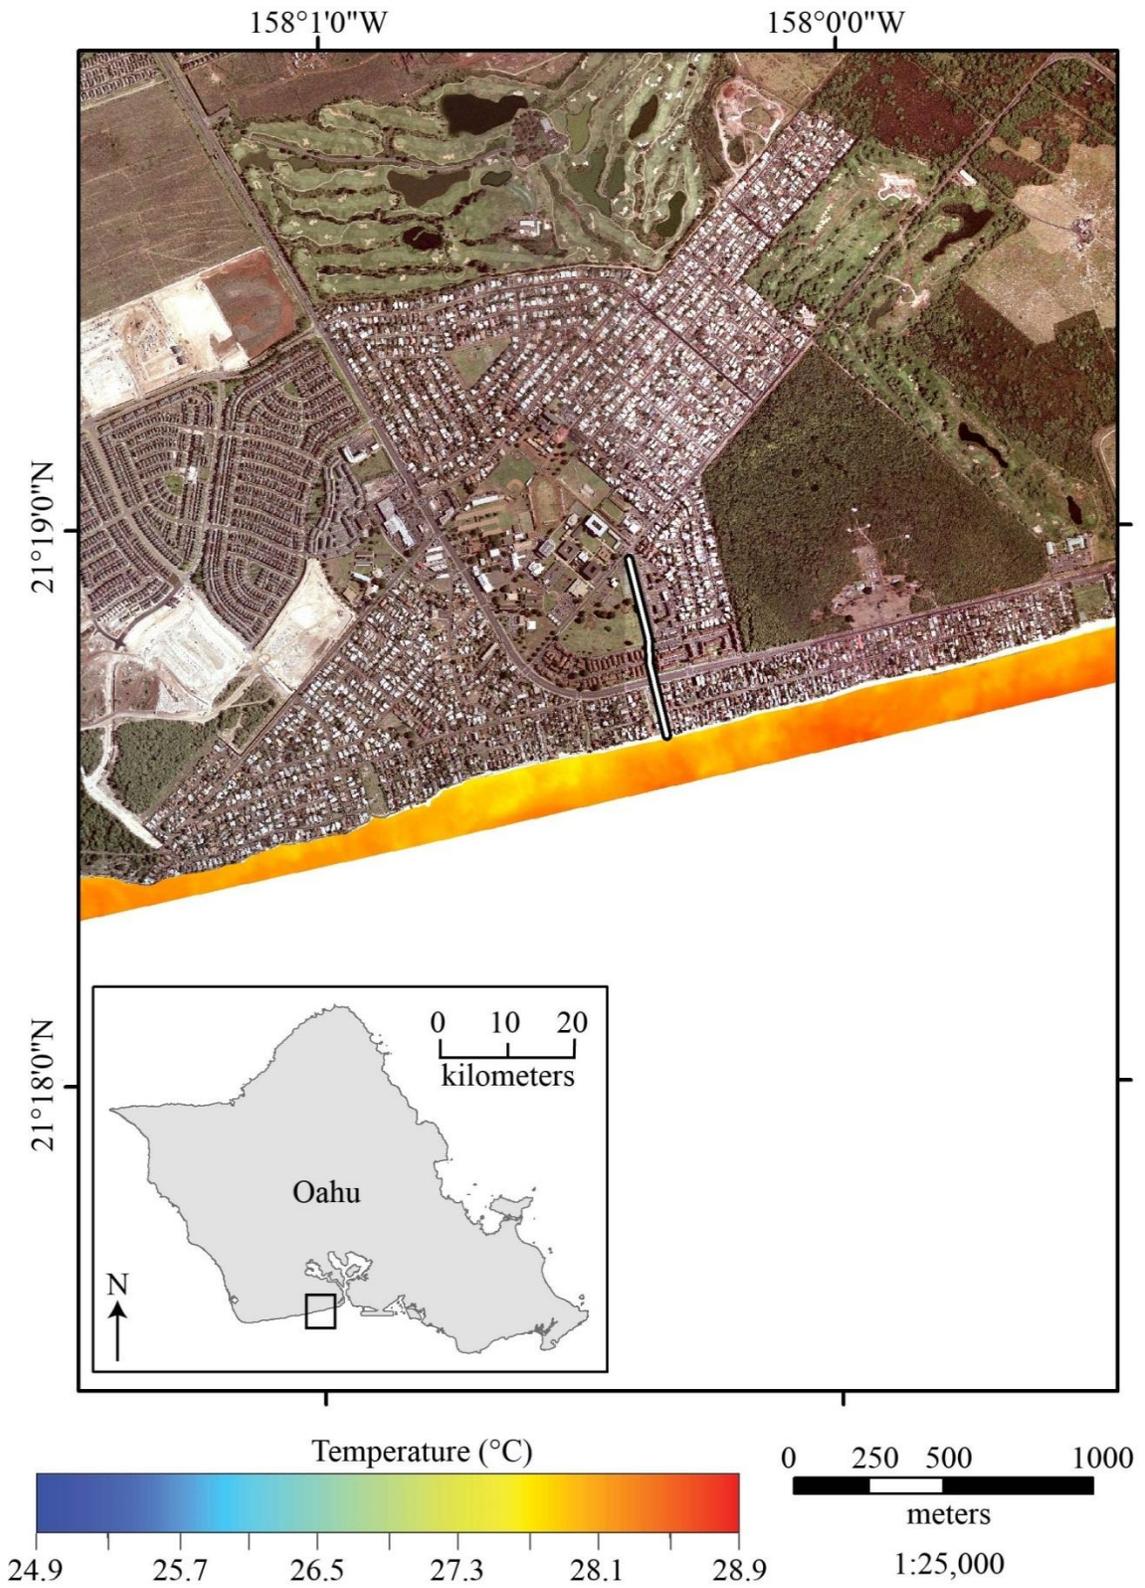

Panel 22: Kalaeloa Airport from 6 July 2009 at 02:49-02:55 a.m., HST. Honolulu tide was +0.17 to +0.18 m MLLW.

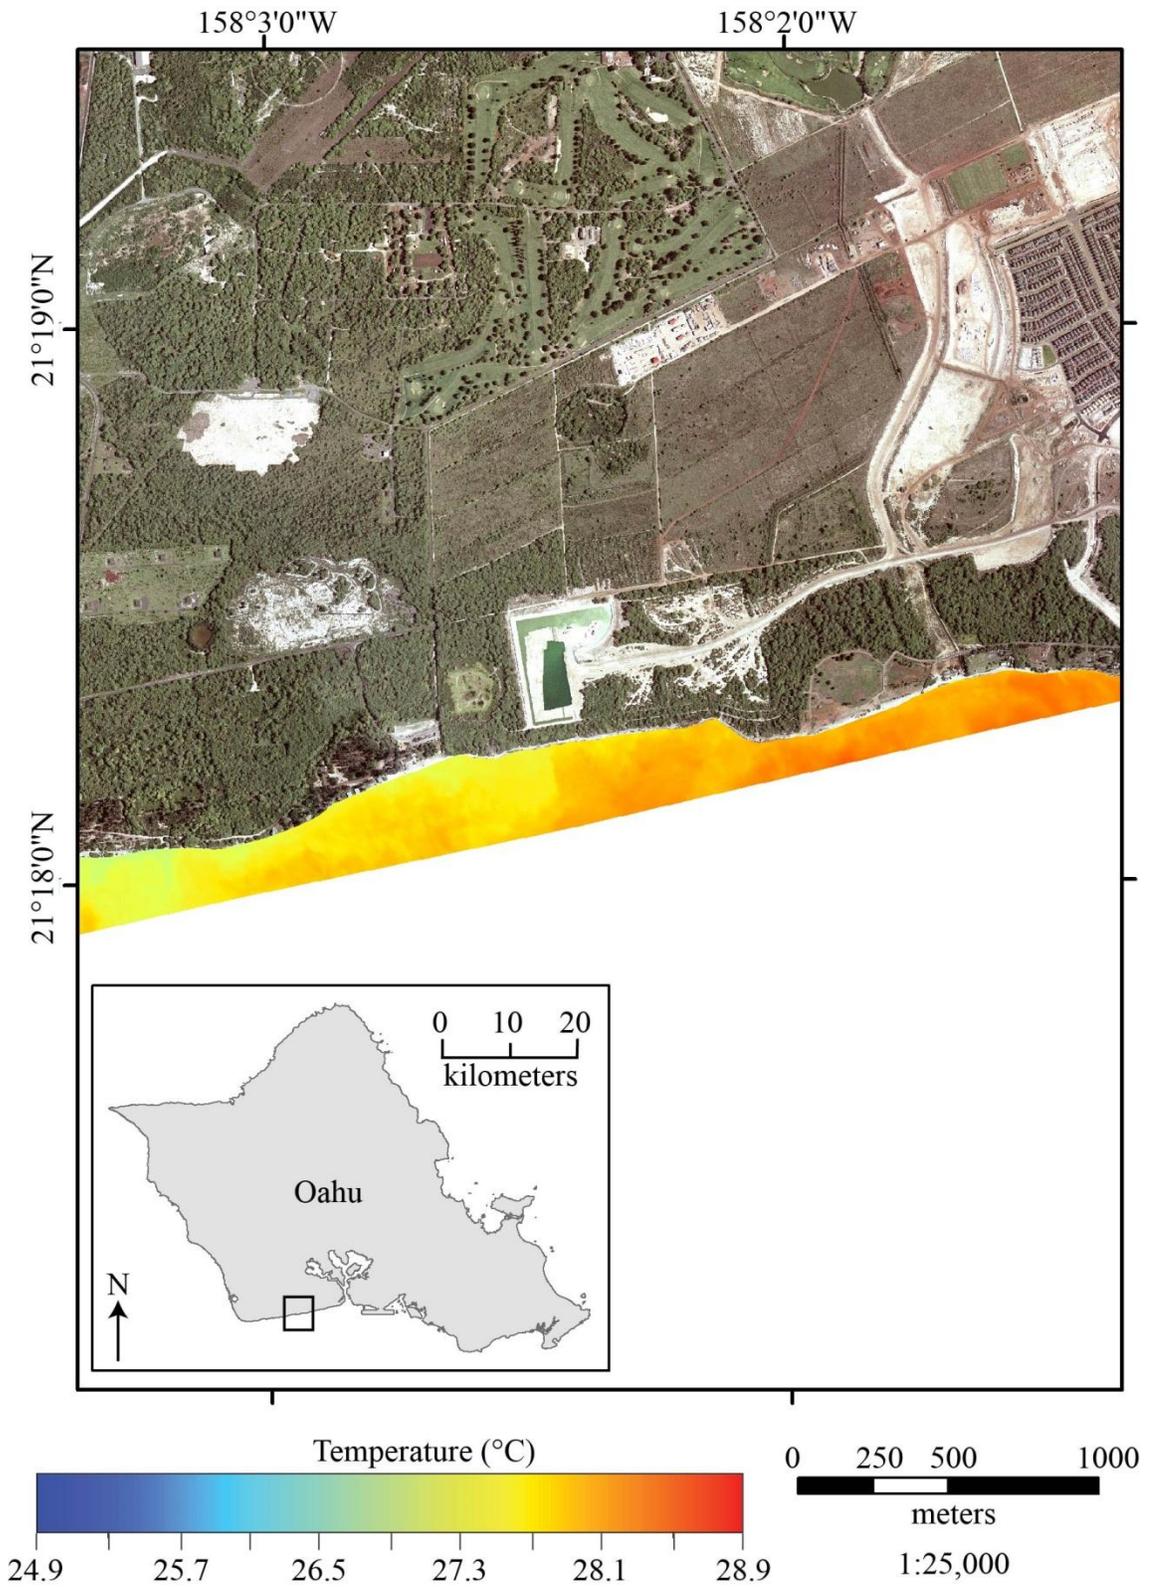

Panel 23: Kalaeloa Regional Park from 6 July 2009 at 02:49-02:55 a.m., HST. Honolulu tide was +0.17 to +0.18 m MLLW.

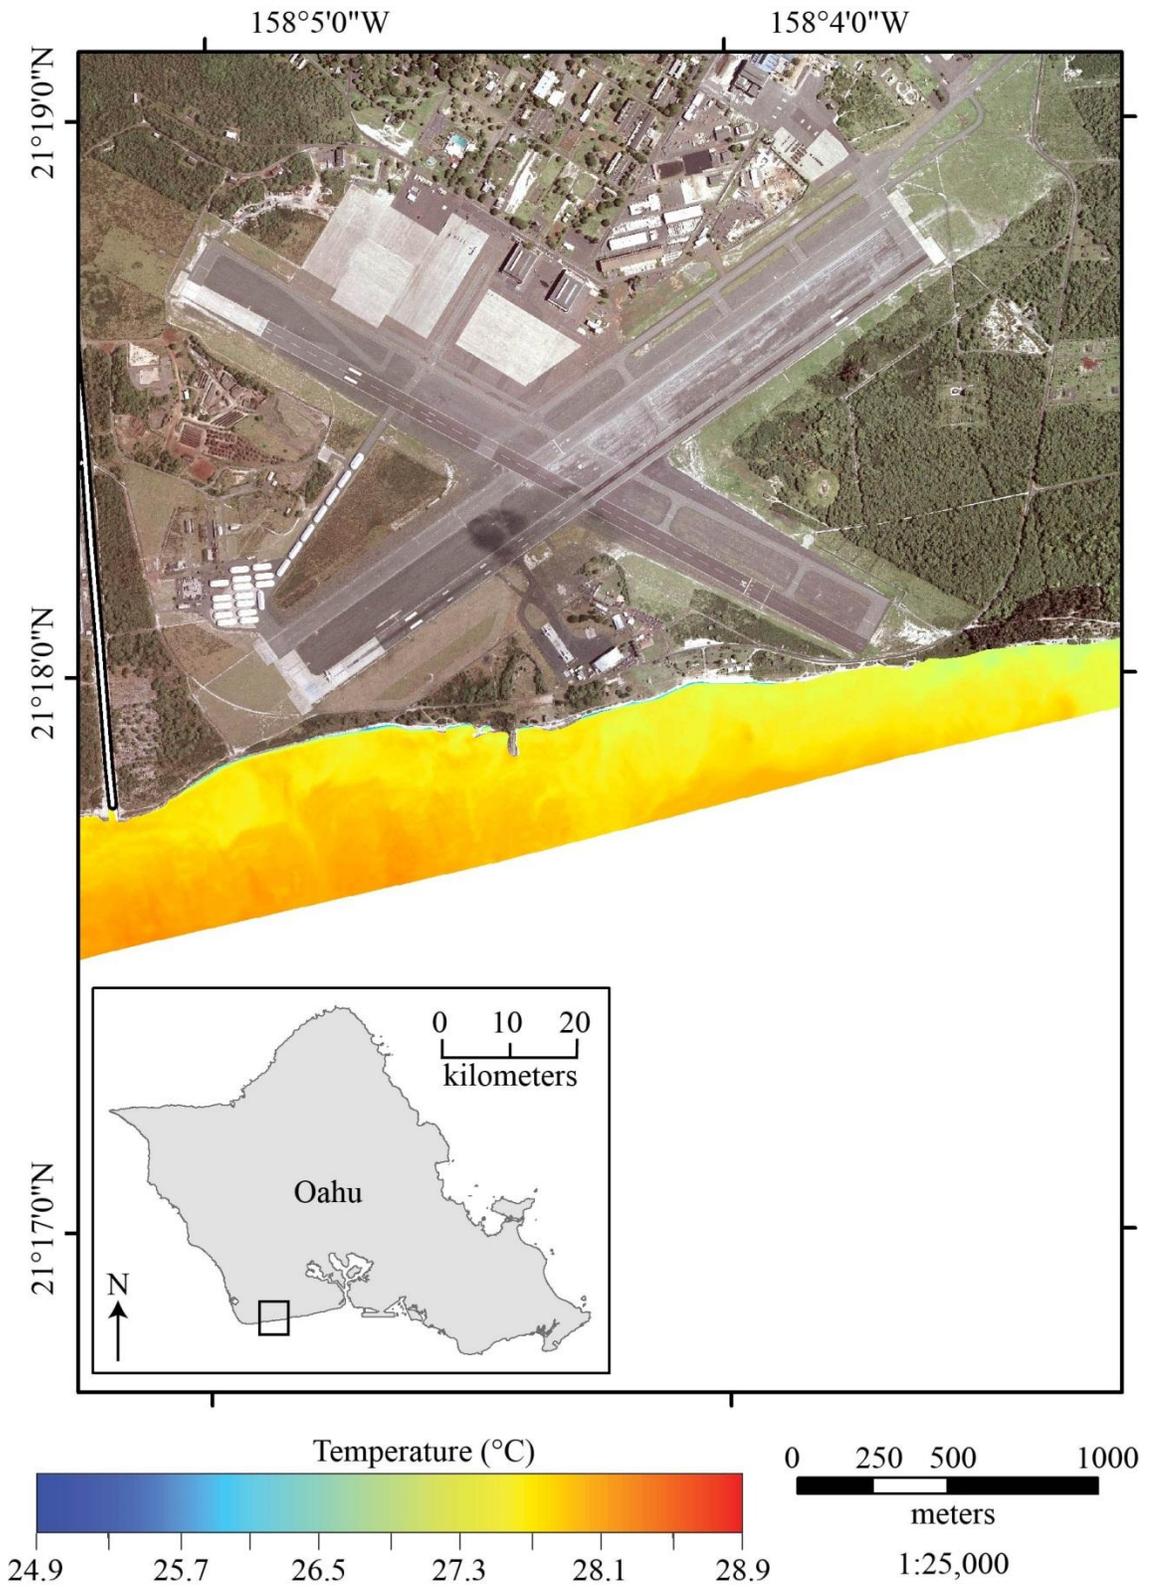

Panel 24: Mouth of Pearl Harbor from 12 June 2009 at 06:36-06:38 a.m., HST. Honolulu tide was +0.16 m MLLW.

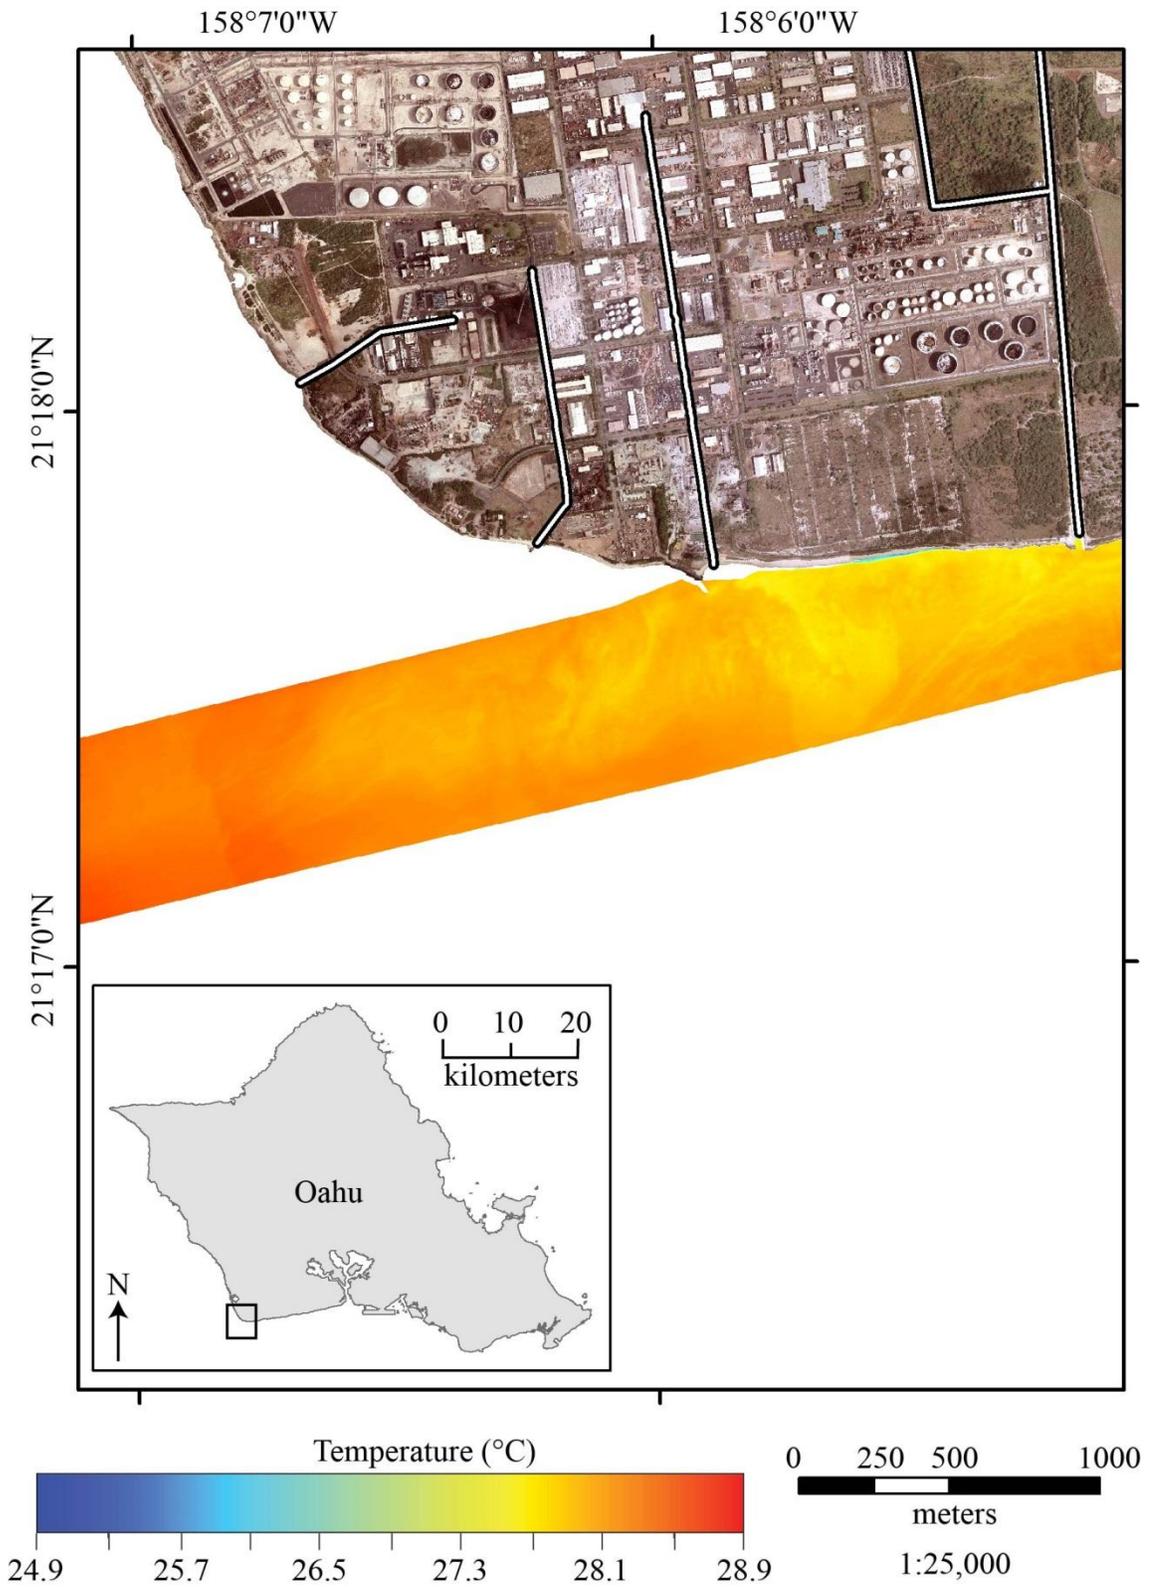

Panel 25: Ewa Beach from 12 June 2009 at 06:36-06:38 a.m., HST. Honolulu tide was +0.16 m MLLW.

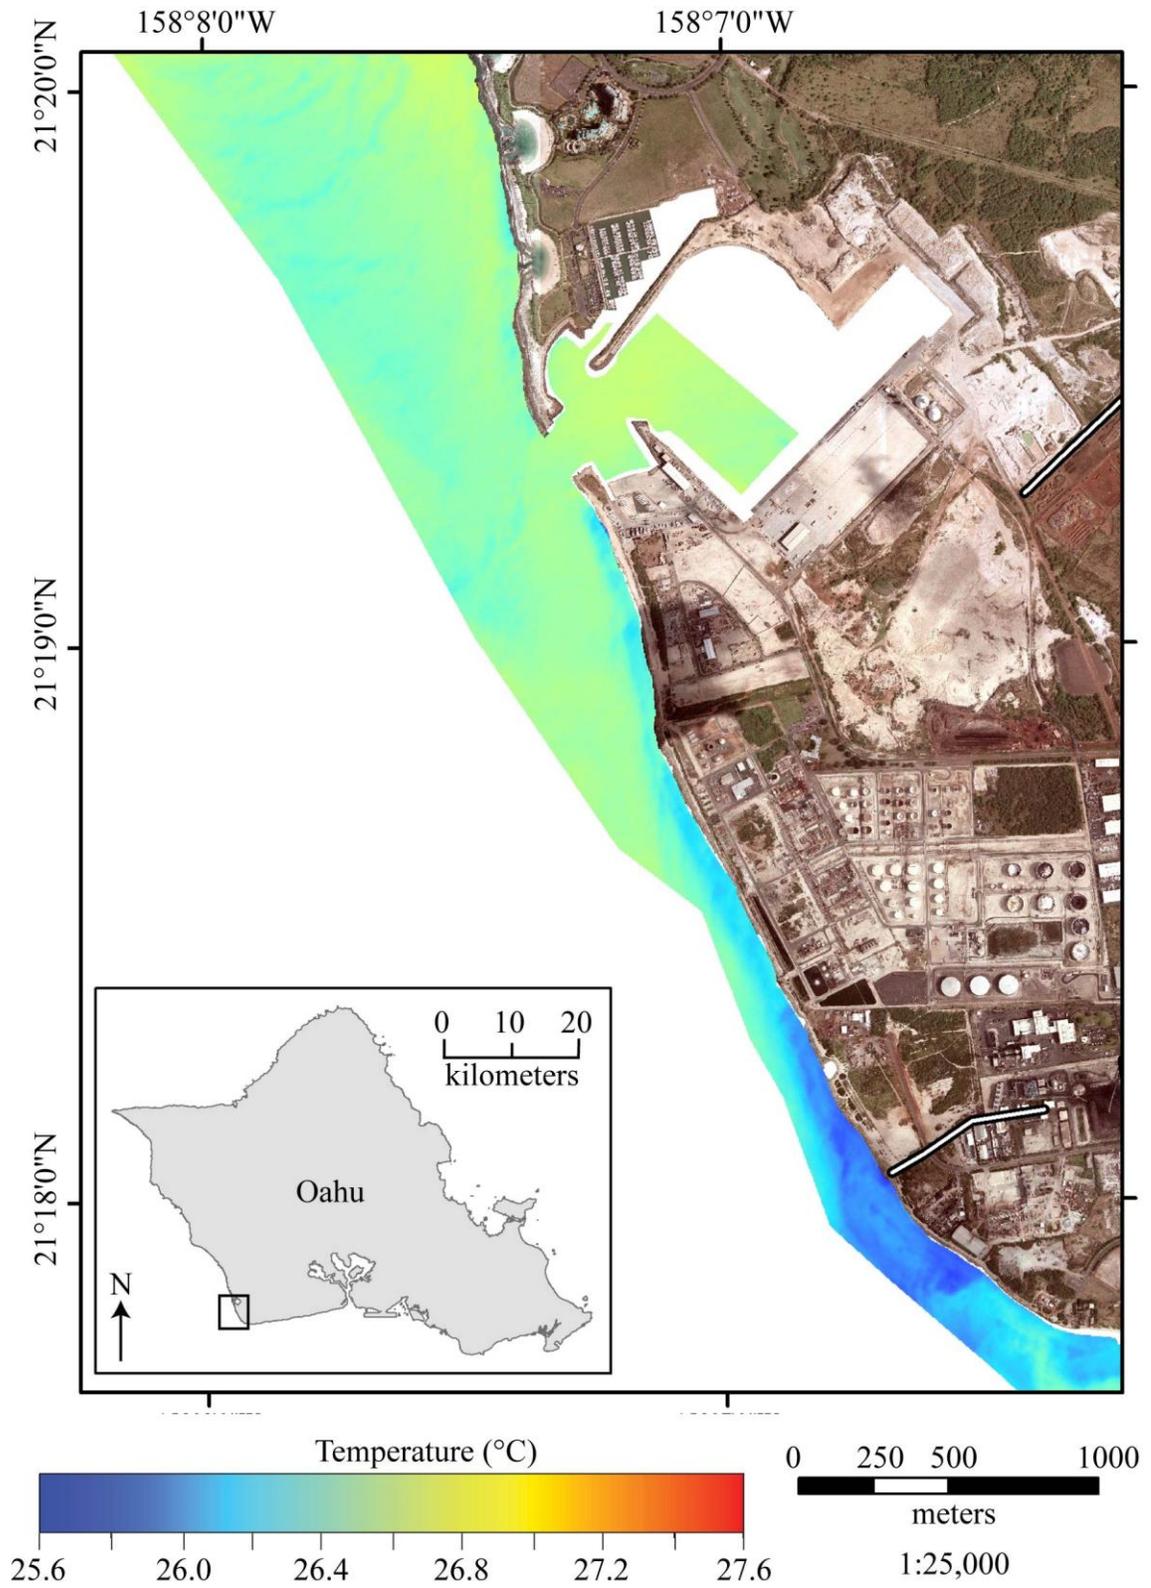

Panel 26: Oneula Beach Park from 12 June 2009 at 06:36-06:38 a.m., HST. Honolulu tide was +0.16 m MLLW.

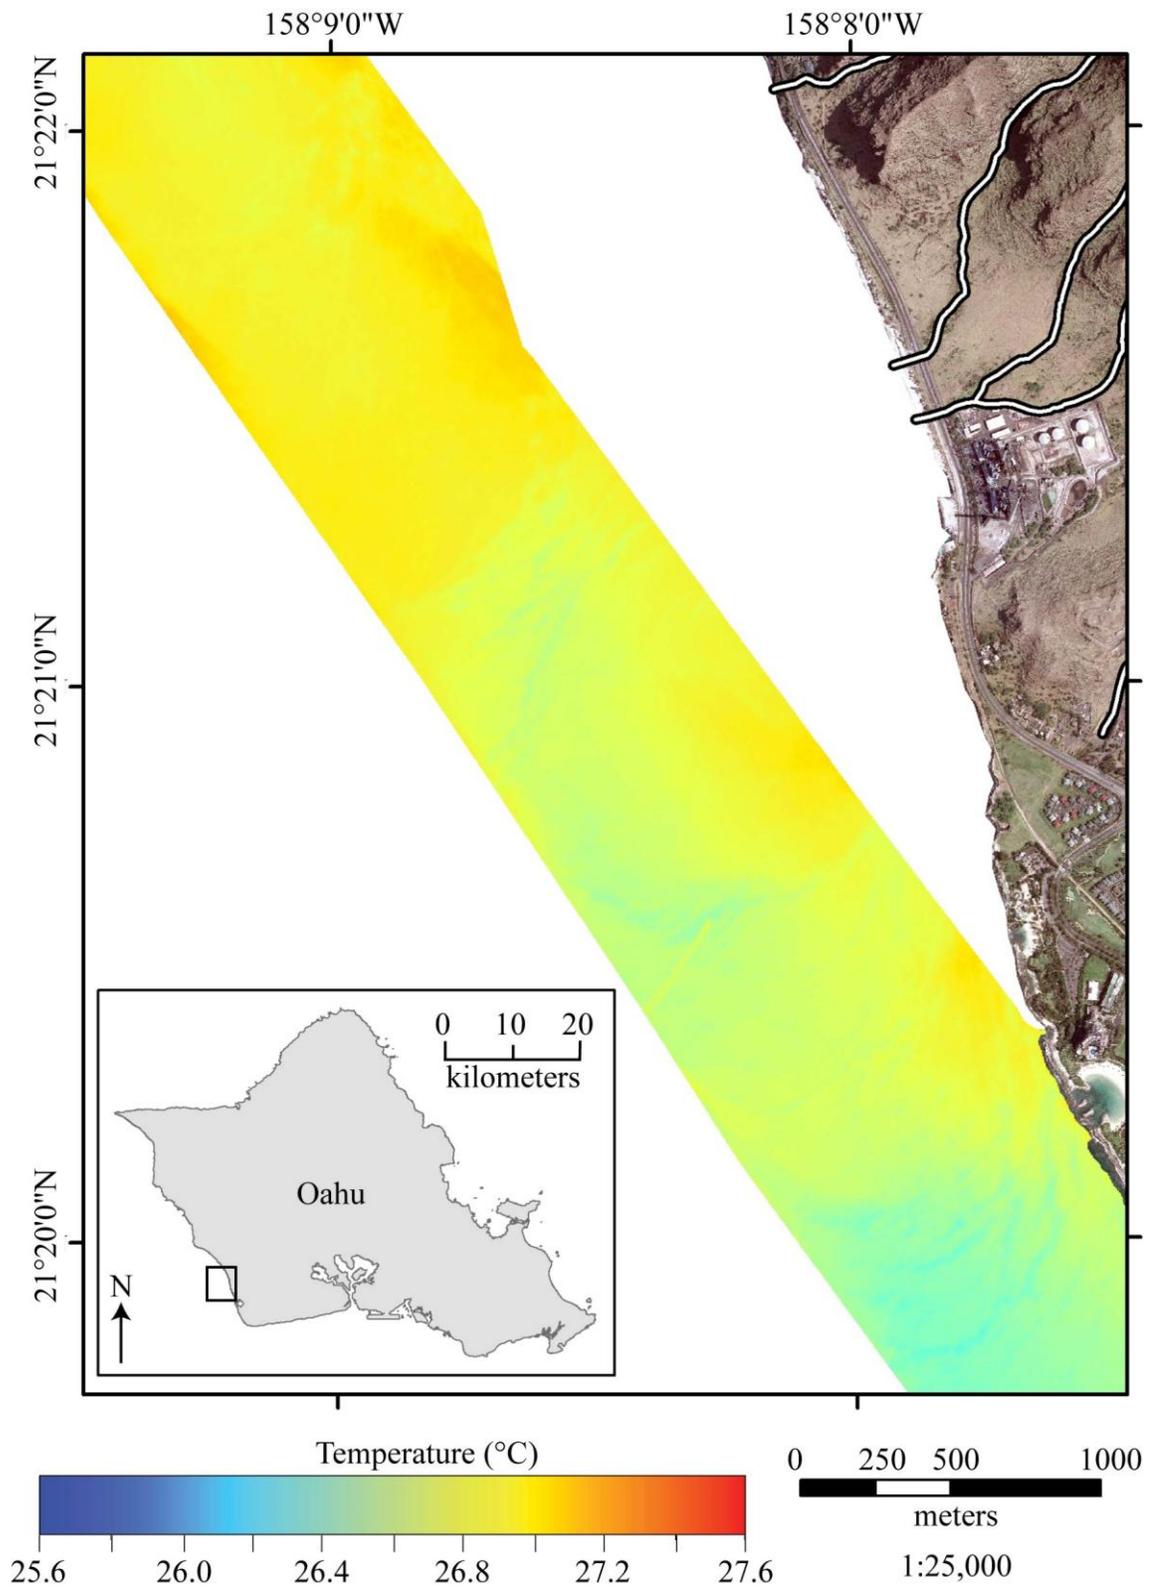

Panel 27: Kalaeloa Airport from 12 June 2009 at 06:36-06:38 a.m., HST. Honolulu tide was +0.16 m MLLW.

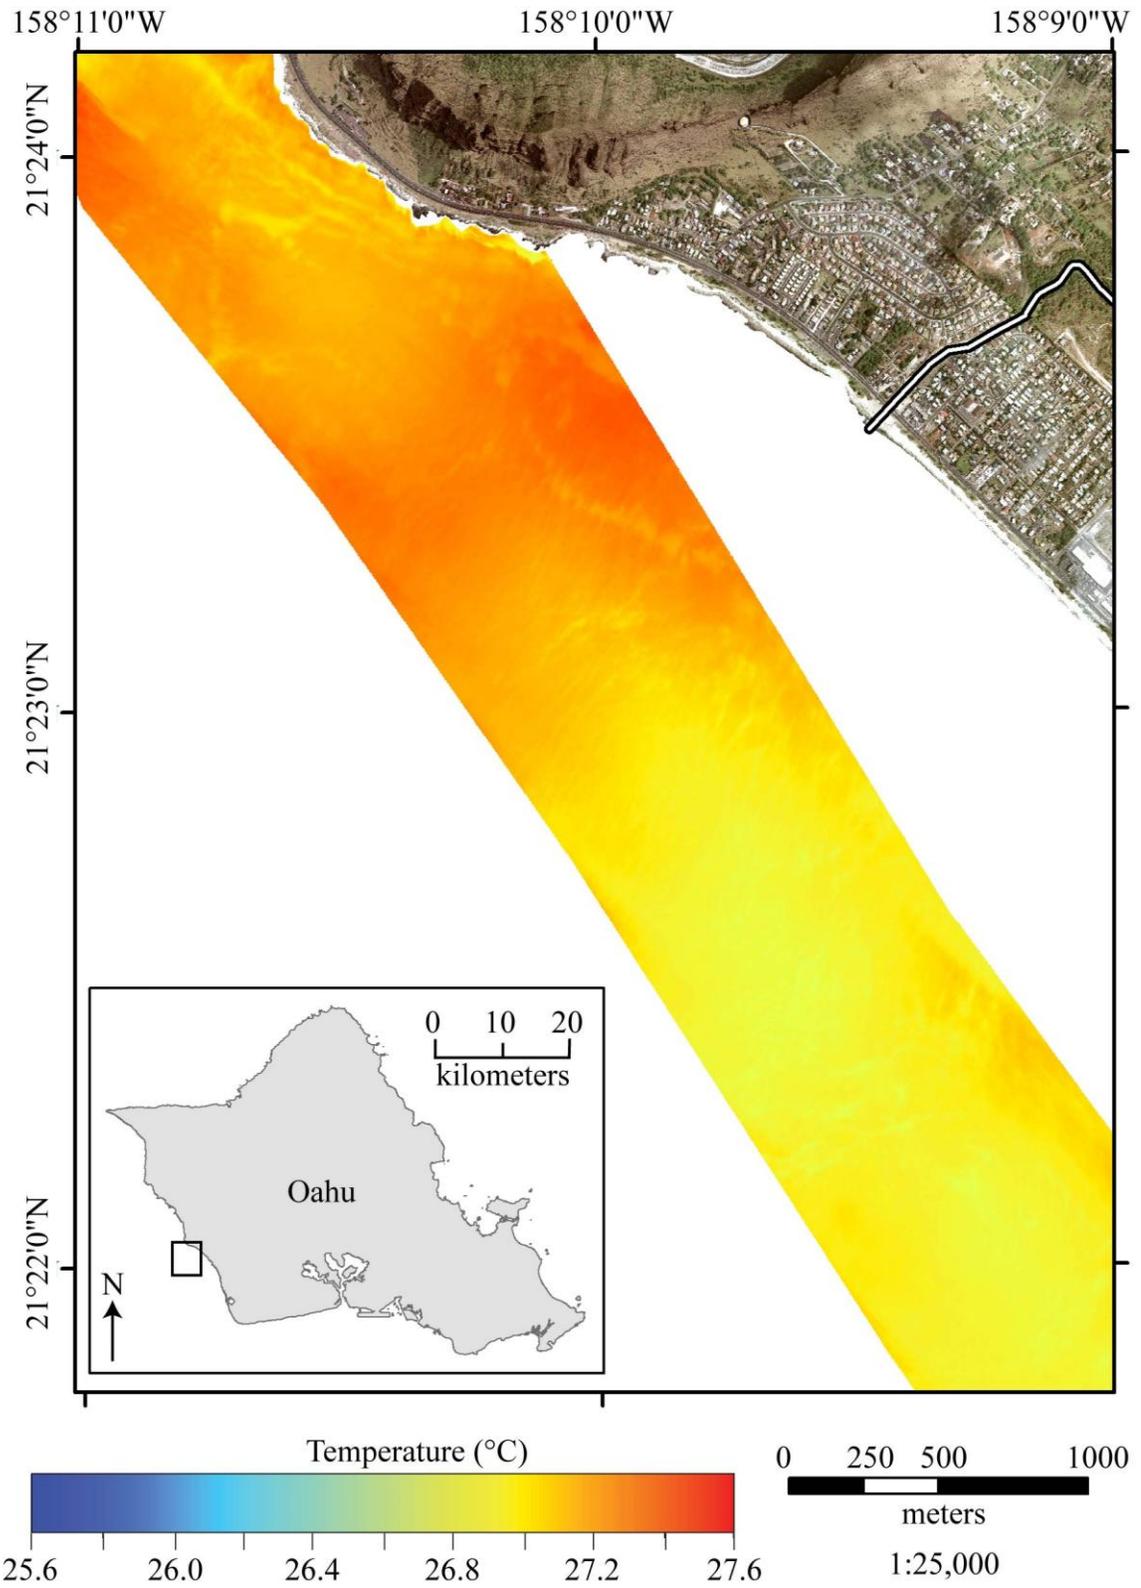

Panel 28: Kalaeloa Regional Park from 12 June 2009 at 06:36-06:38 a.m., HST. Honolulu tide was +0.16 m MLLW.

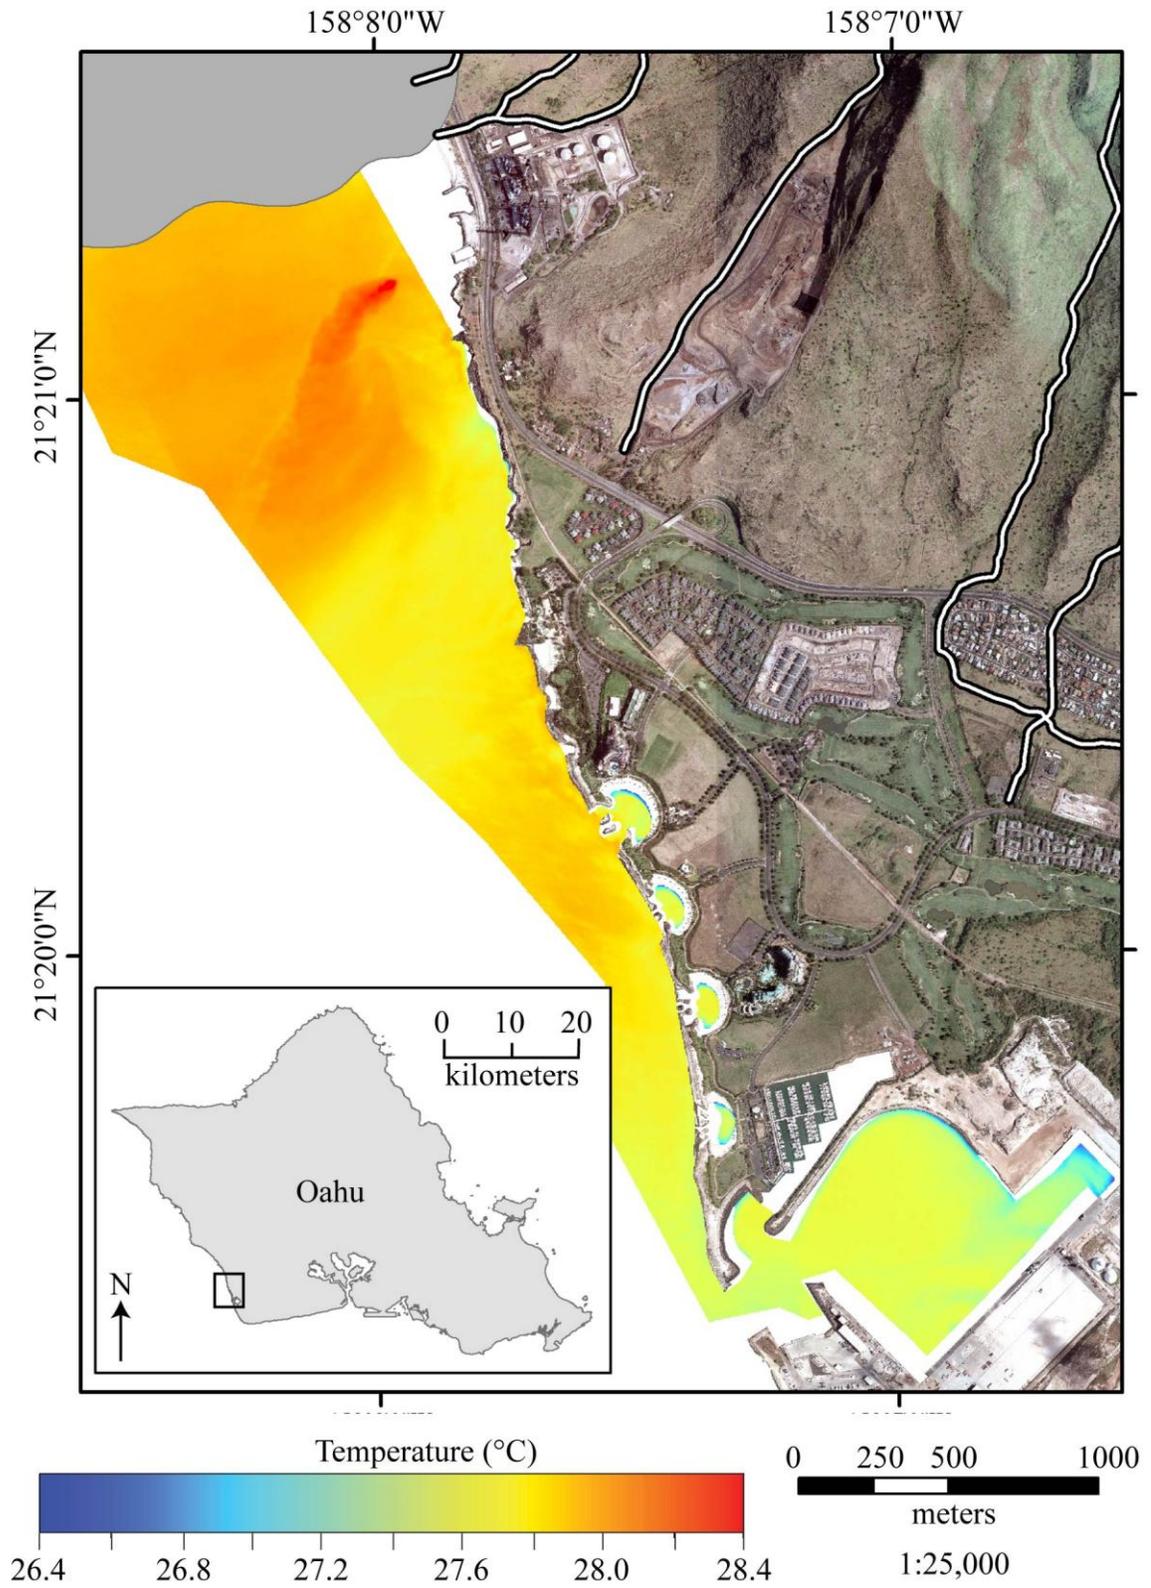

Panel 29: Barber's Point Deep Draft Harbor from 6 July 2009 at 03:06-03:13 a.m., HST. Honolulu tide was +0.18 m MLLW.

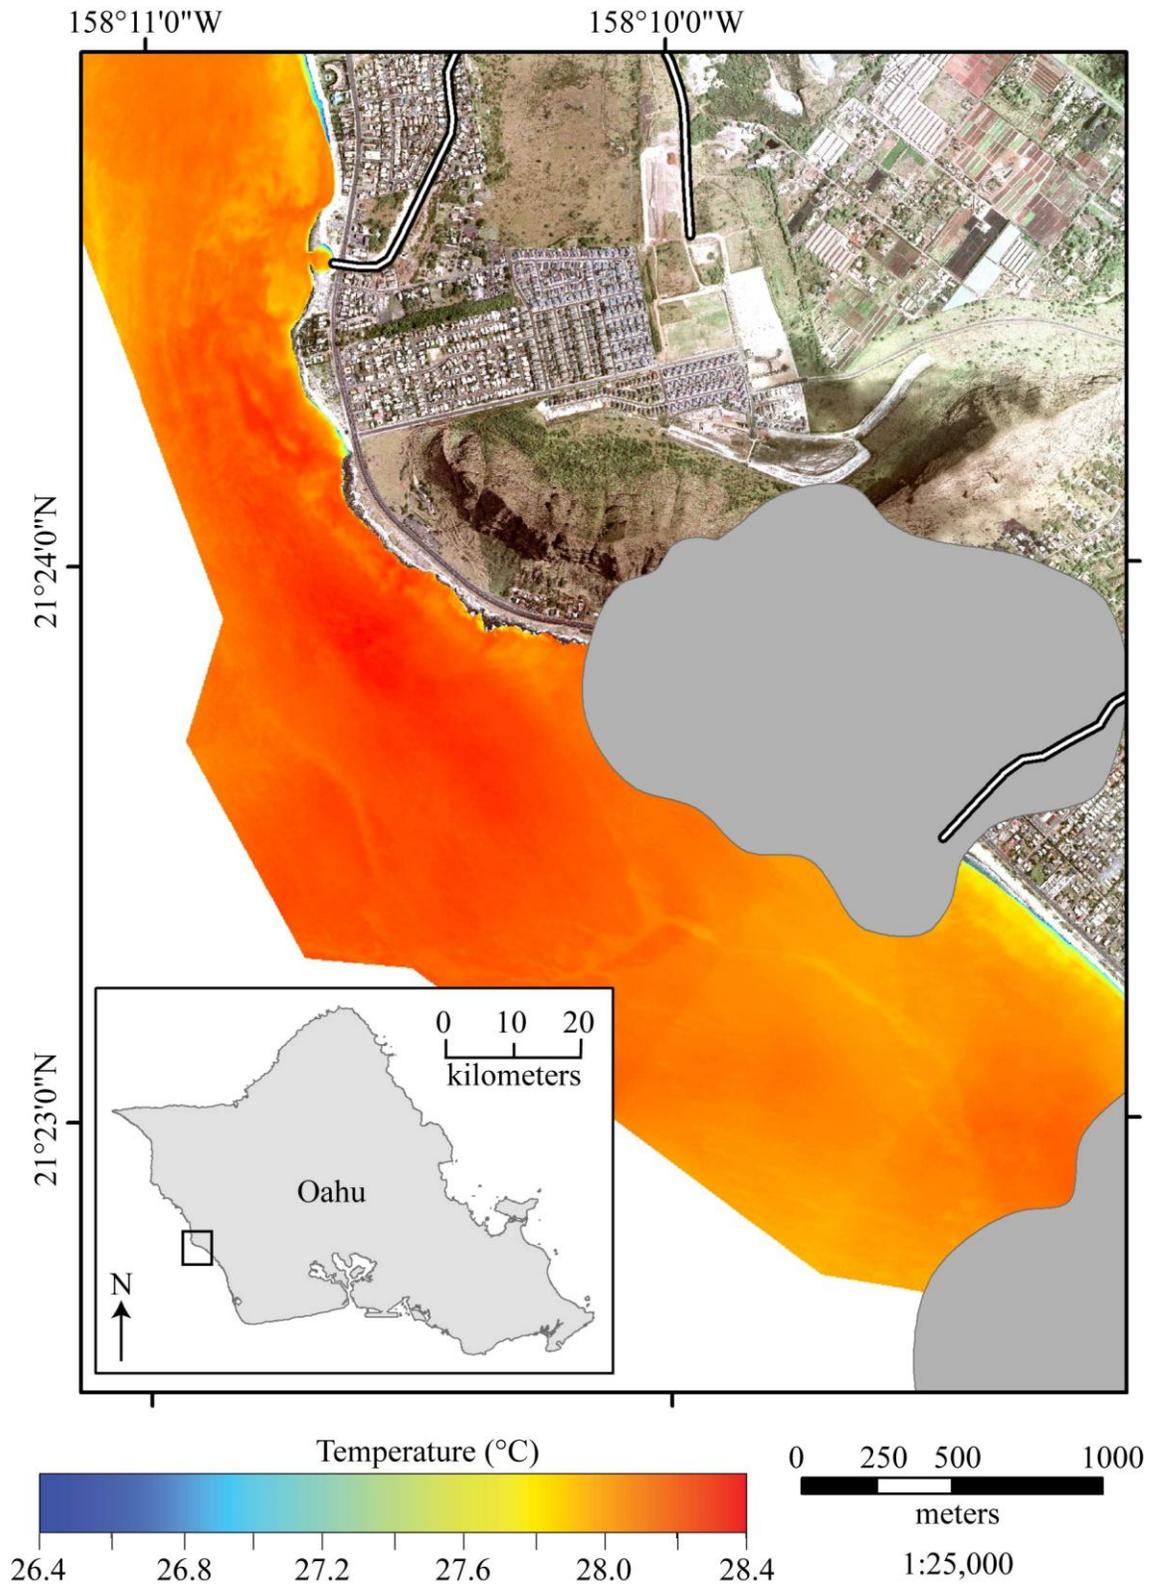

Panel 30: Kahe Point from 6 July 2009 at 03:06-03:13 a.m., HST. Honolulu tide was +0.18 m MLLW.

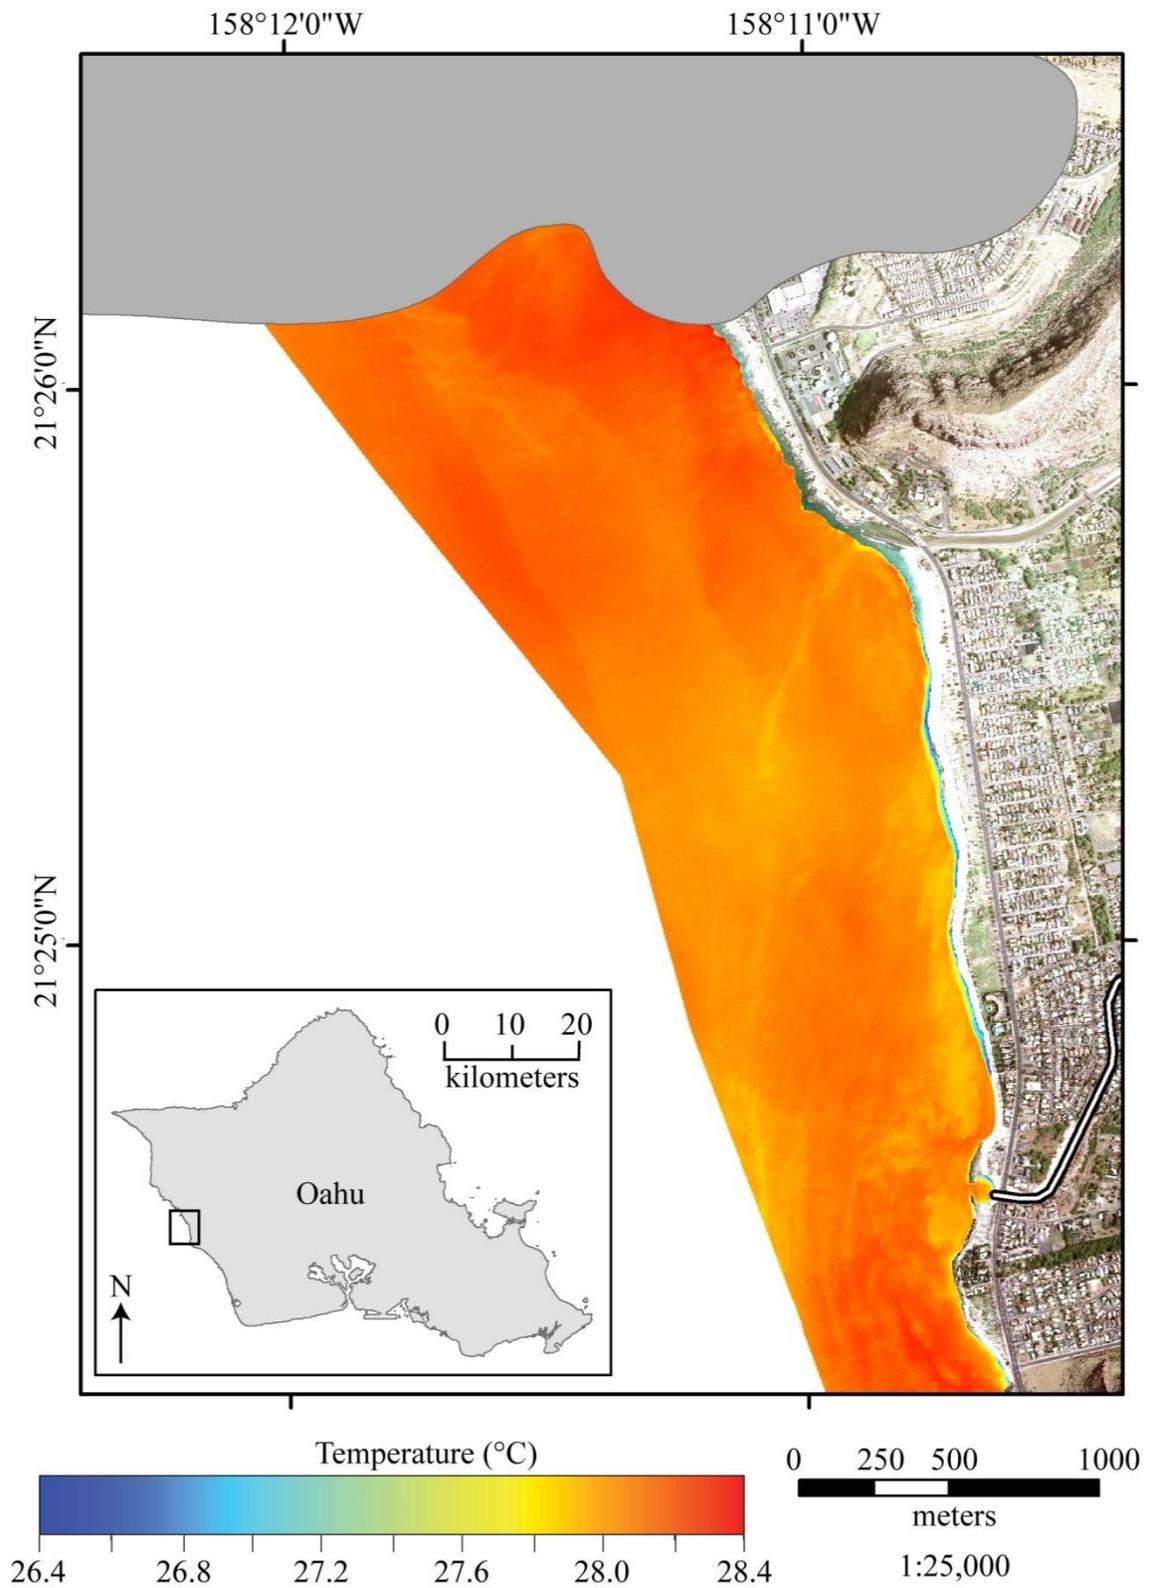

Panel 31: Nanakuli from 6 July 2009 at 03:06-03:13 a.m., HST. Honolulu tide was +0.18 m MLLW.

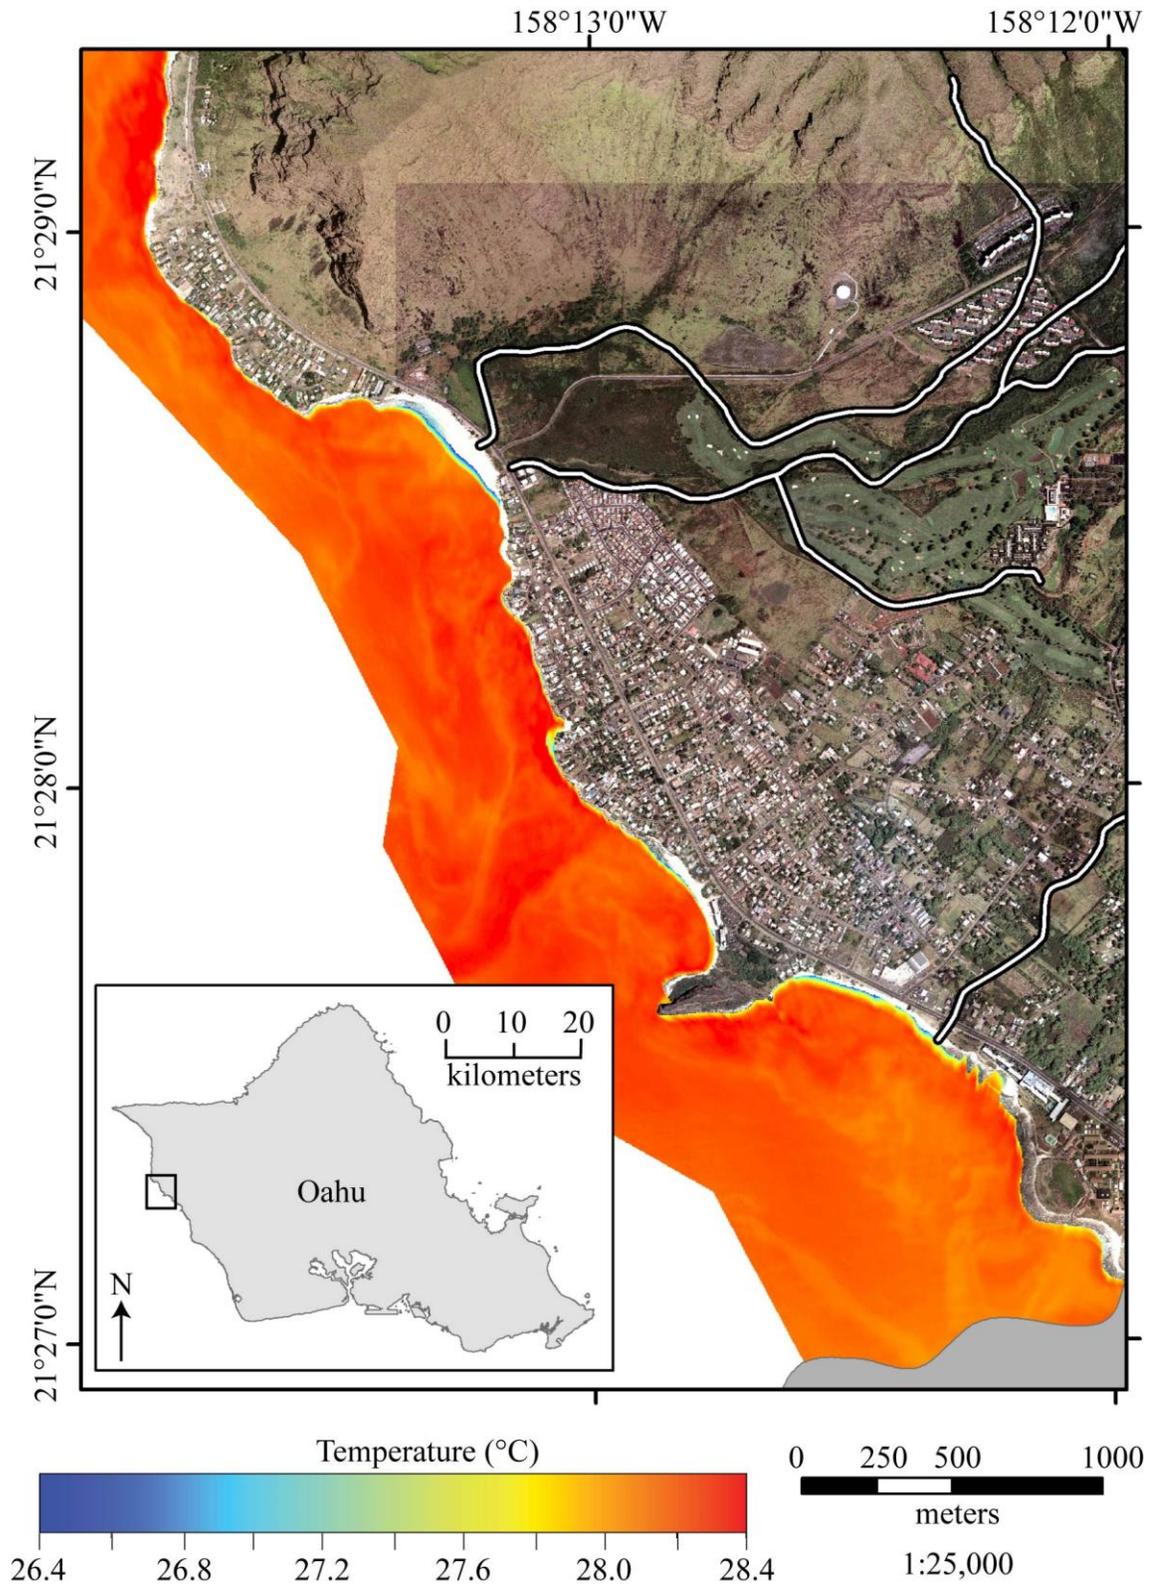

Panel 32: Barber's Point Deep Draft Harbor and Kahe Point from 17 July 2009 from 04:51-04:59 a.m., HST. Honolulu tide was -0.04 m MLLW.

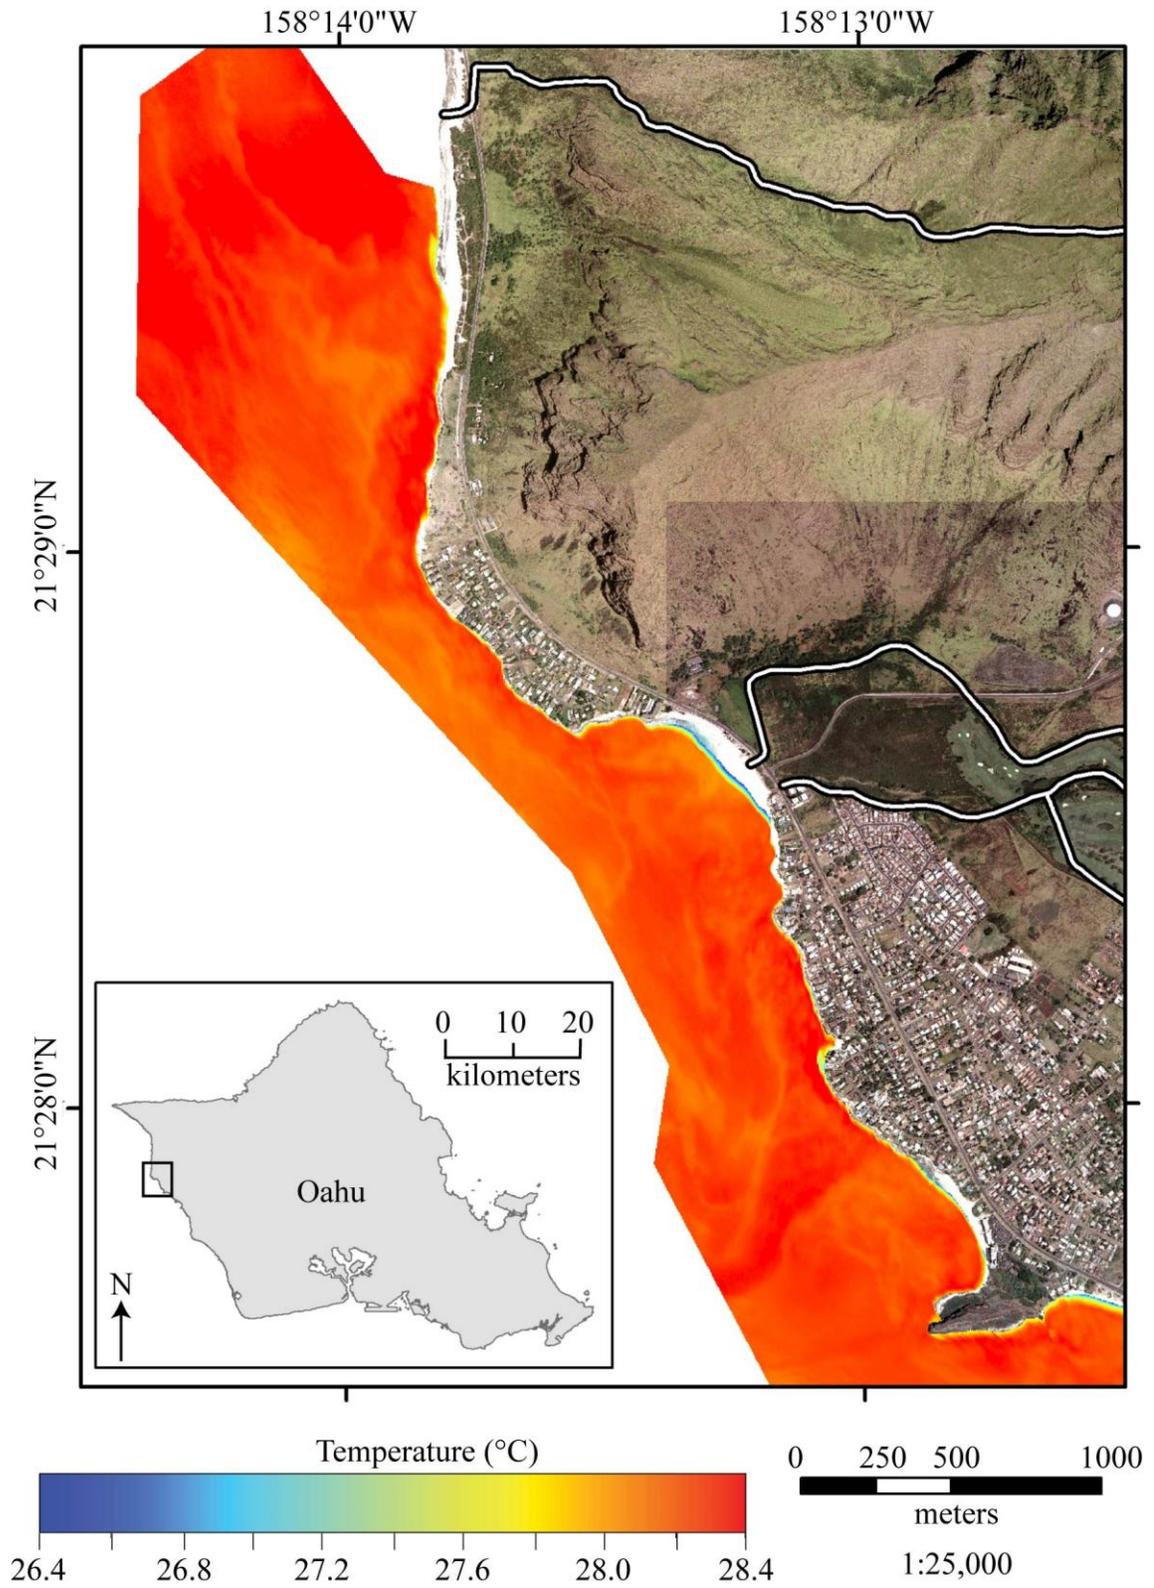

Panel 33: Nanakuli from 17 July 2009 from 04:51-04:59 a.m., HST. Honolulu tide was -0.04 m MLLW.

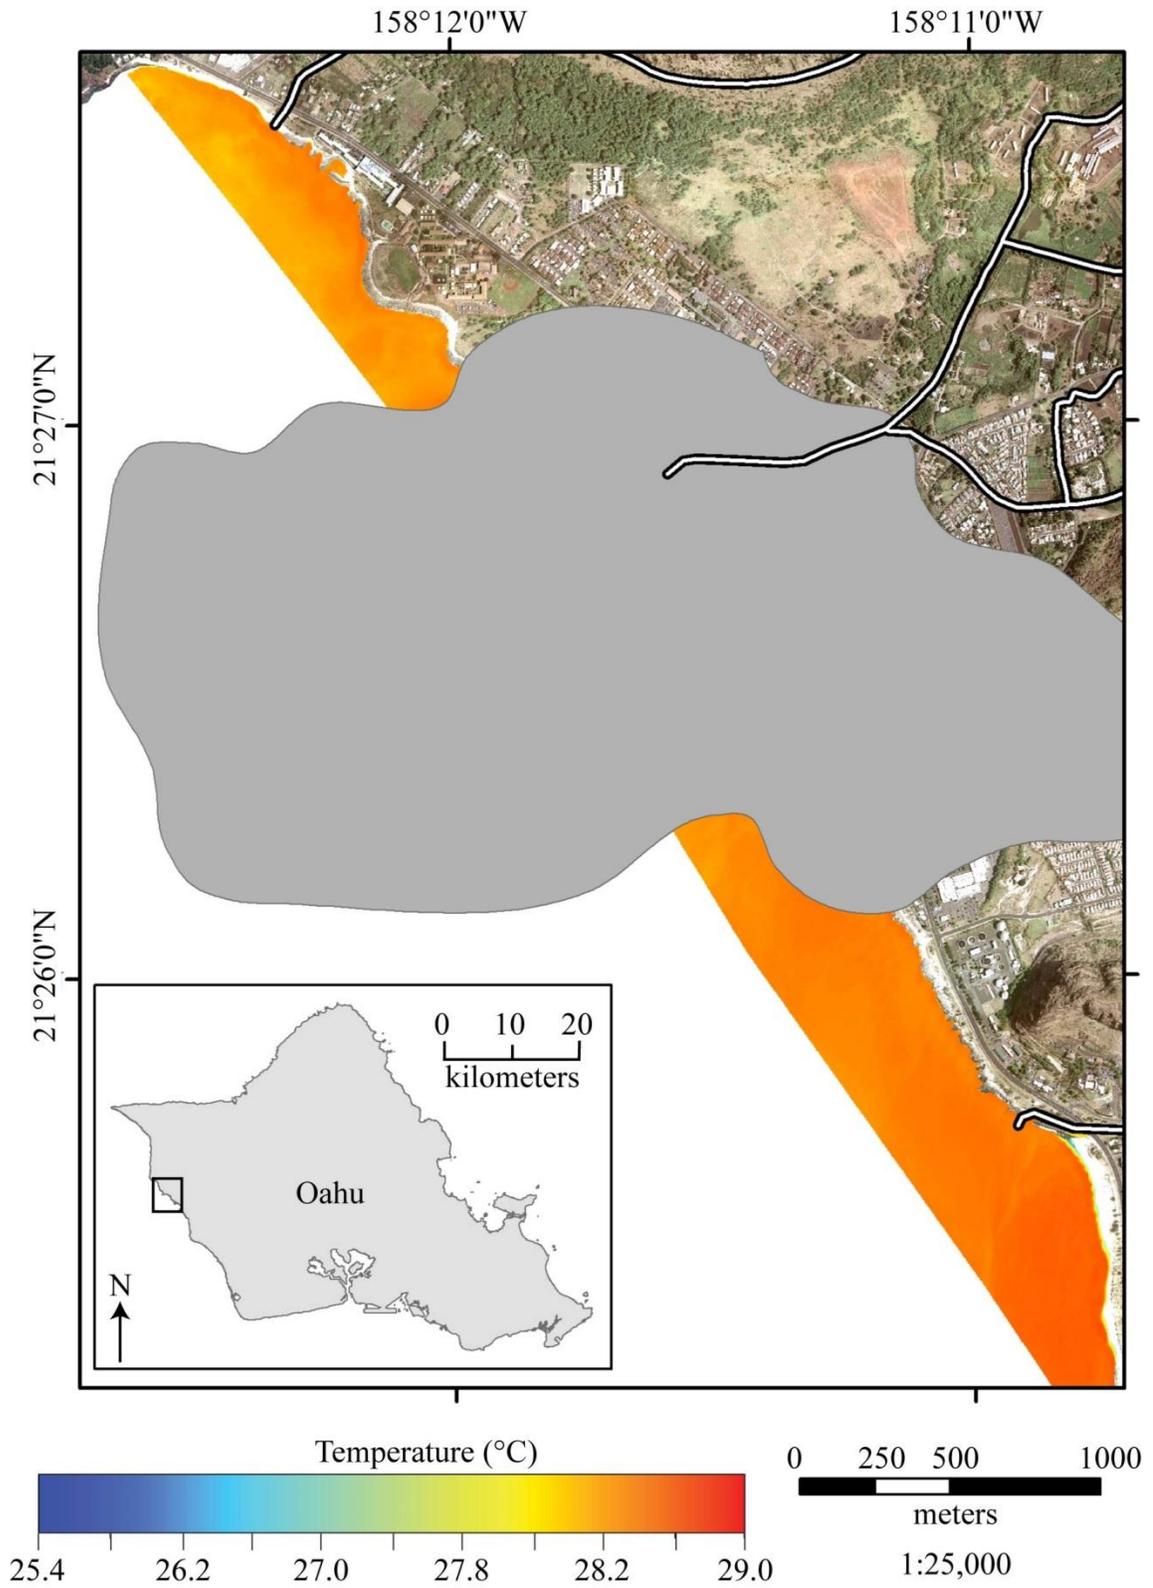

Panel 34: Maili from 17 July 2009 from 04:51-04:59 a.m., HST. Honolulu tide was -0.04 m MLLW.

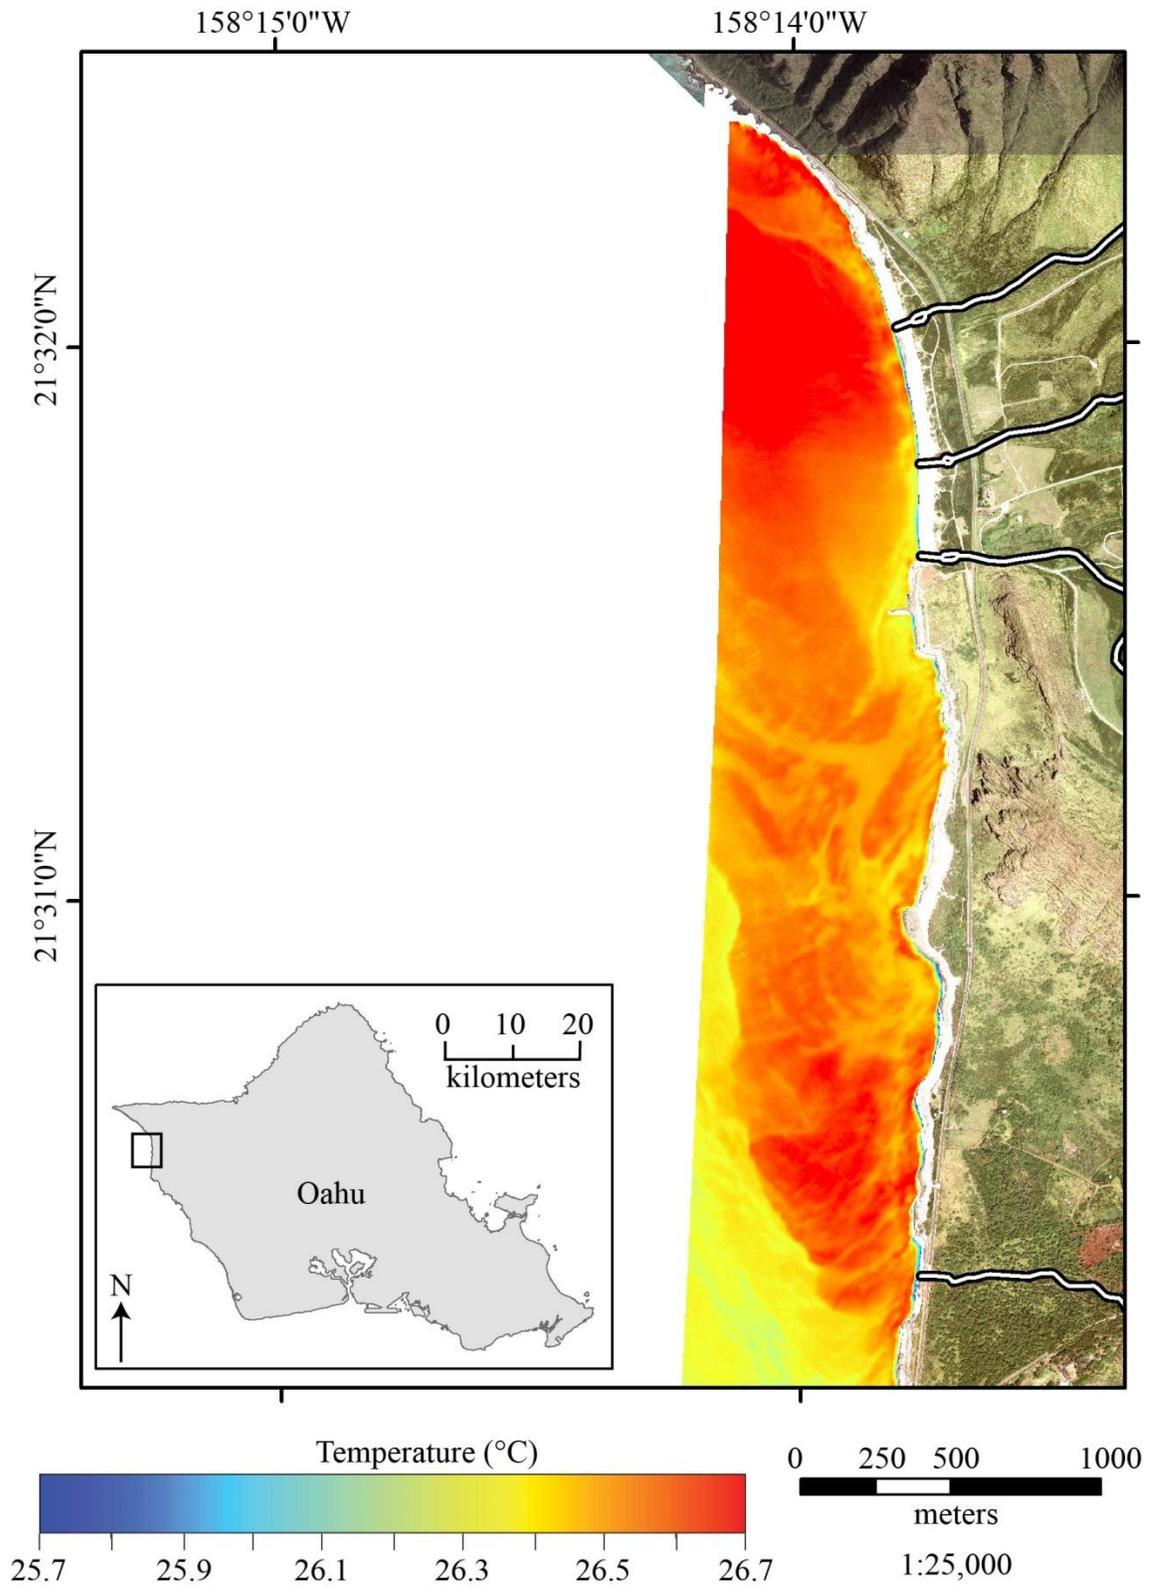

Panel 35: Makaha from 17 July 2009 from 04:51-04:59 a.m., HST. Honolulu tide was -0.04 m MLLW.

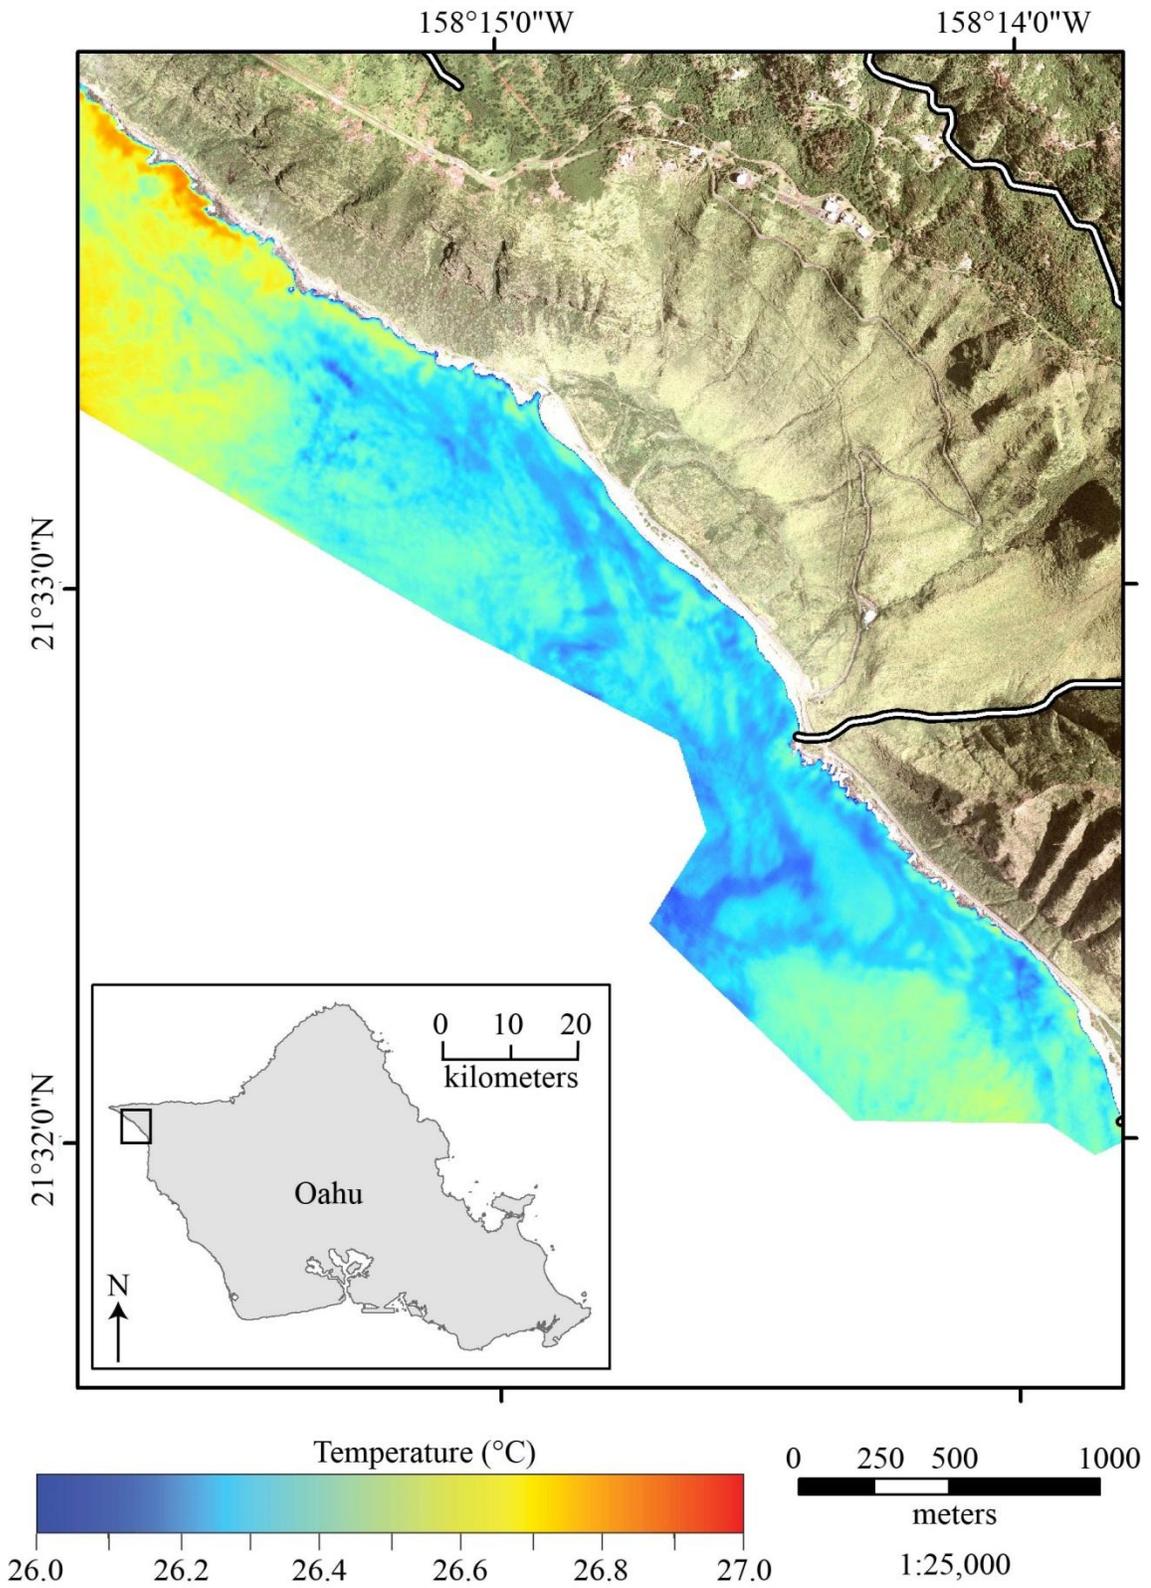

Panel 36: Makaha from 17 July 2009 from 04:51-04:59 a.m., HST. Honolulu tide was -0.04 m MLLW.

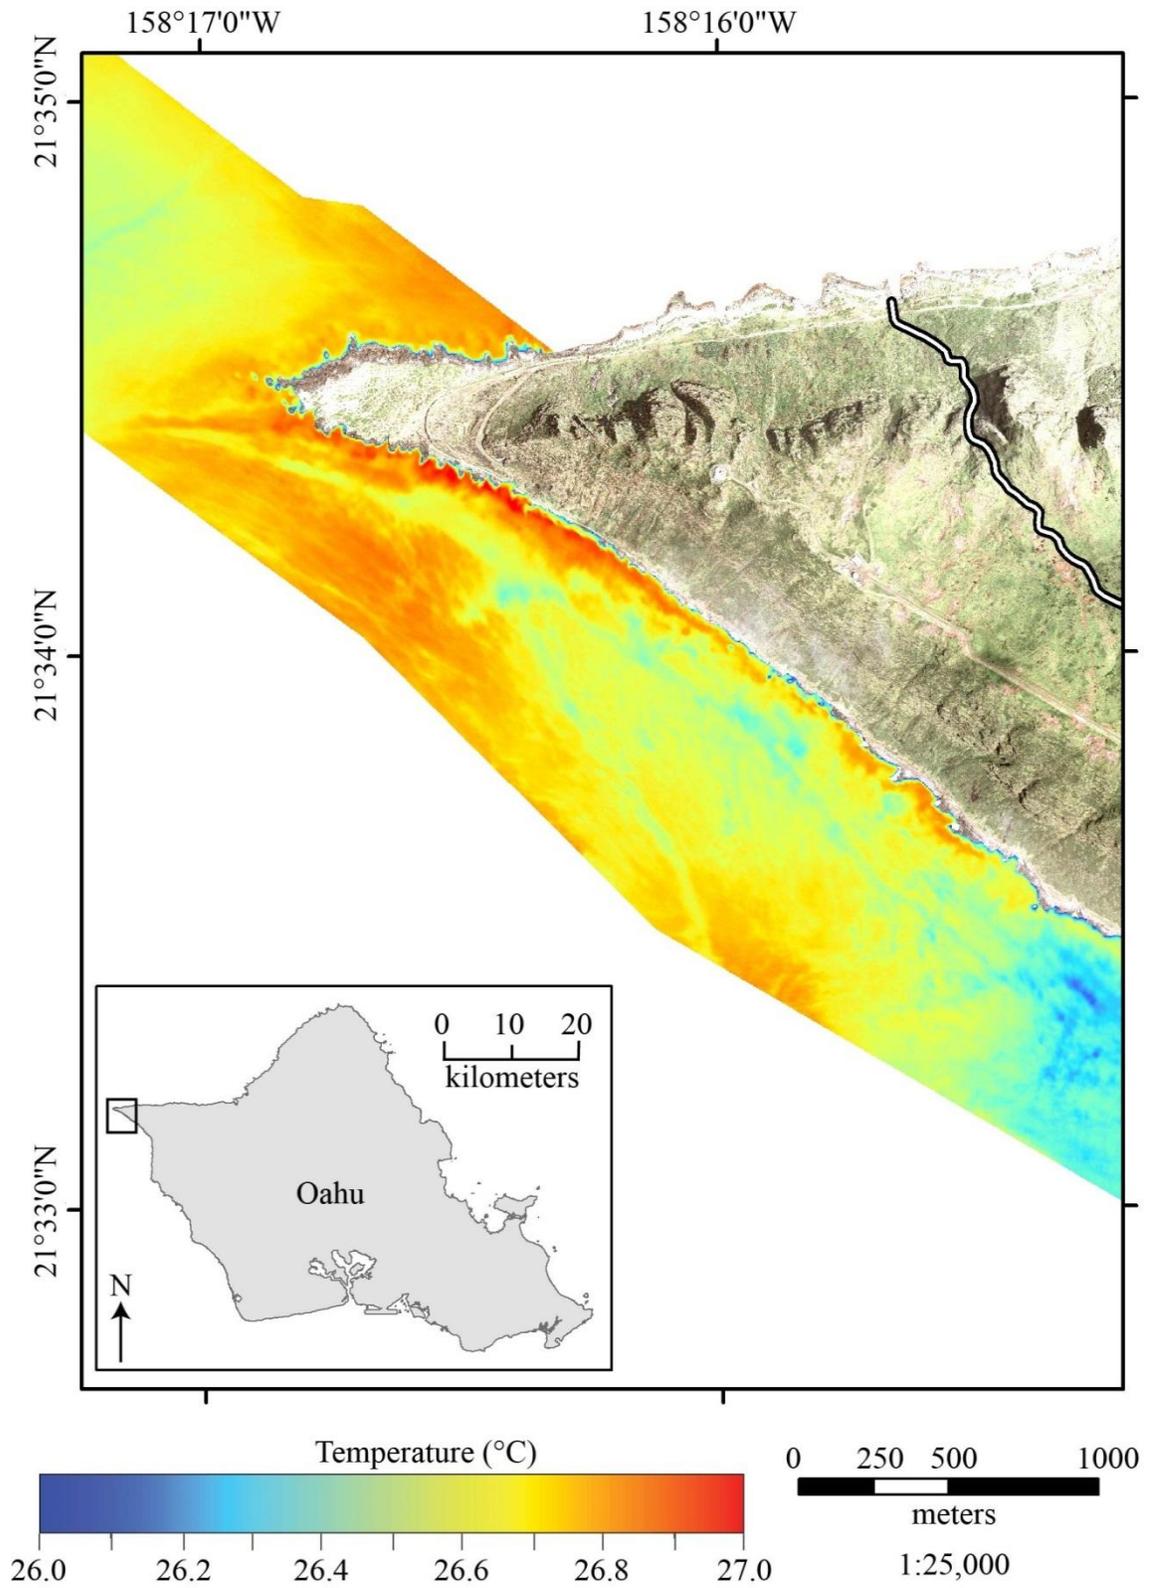

Panel 37: Waianae from 17 July 2009 at 05:24-05:30 a.m., HST. Honolulu tide was -0.04 to -0.03 m MLLW.

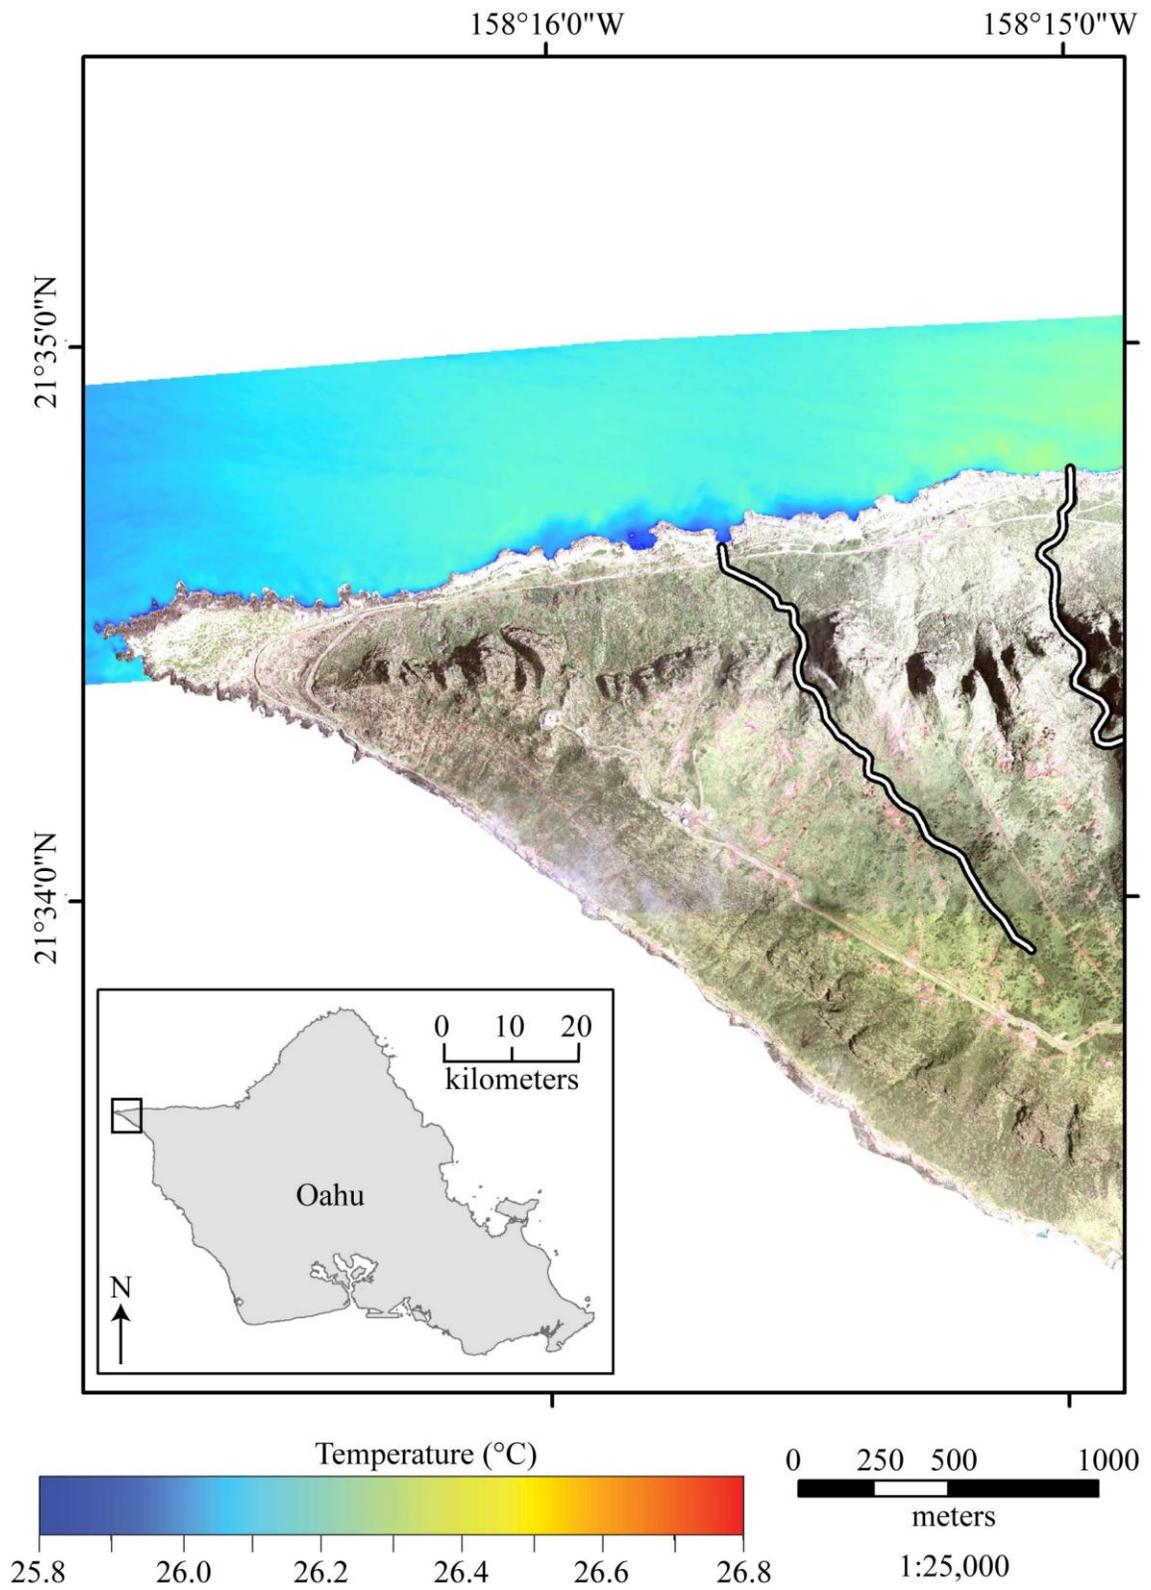

Panel 38: Makua Keaau Forest Reserve from 17 July 2009 at 05:07-05:09 a.m., HST. Honolulu tide was -0.04 m MLLW.

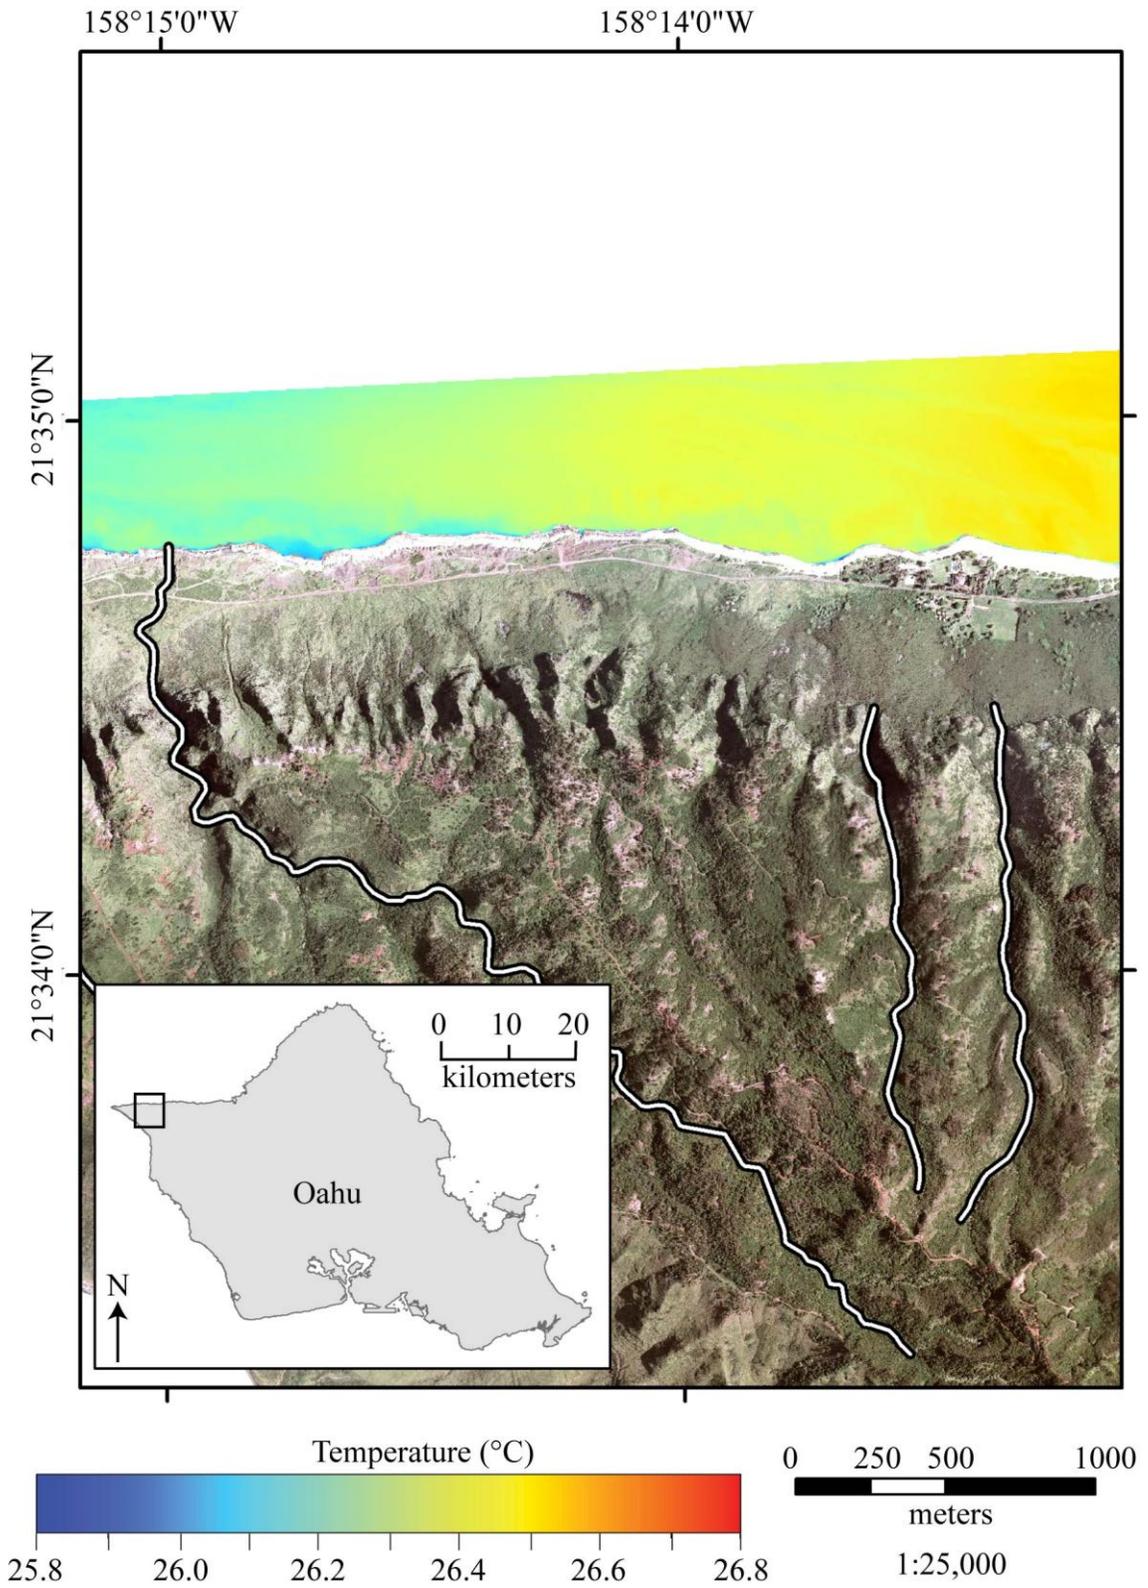

Panel 39: Kaena Point State Natural Area Reserve from 22 July 2009 at 00:30-00:33 a.m., HST. Honolulu tide was +0.05 m MLLW.

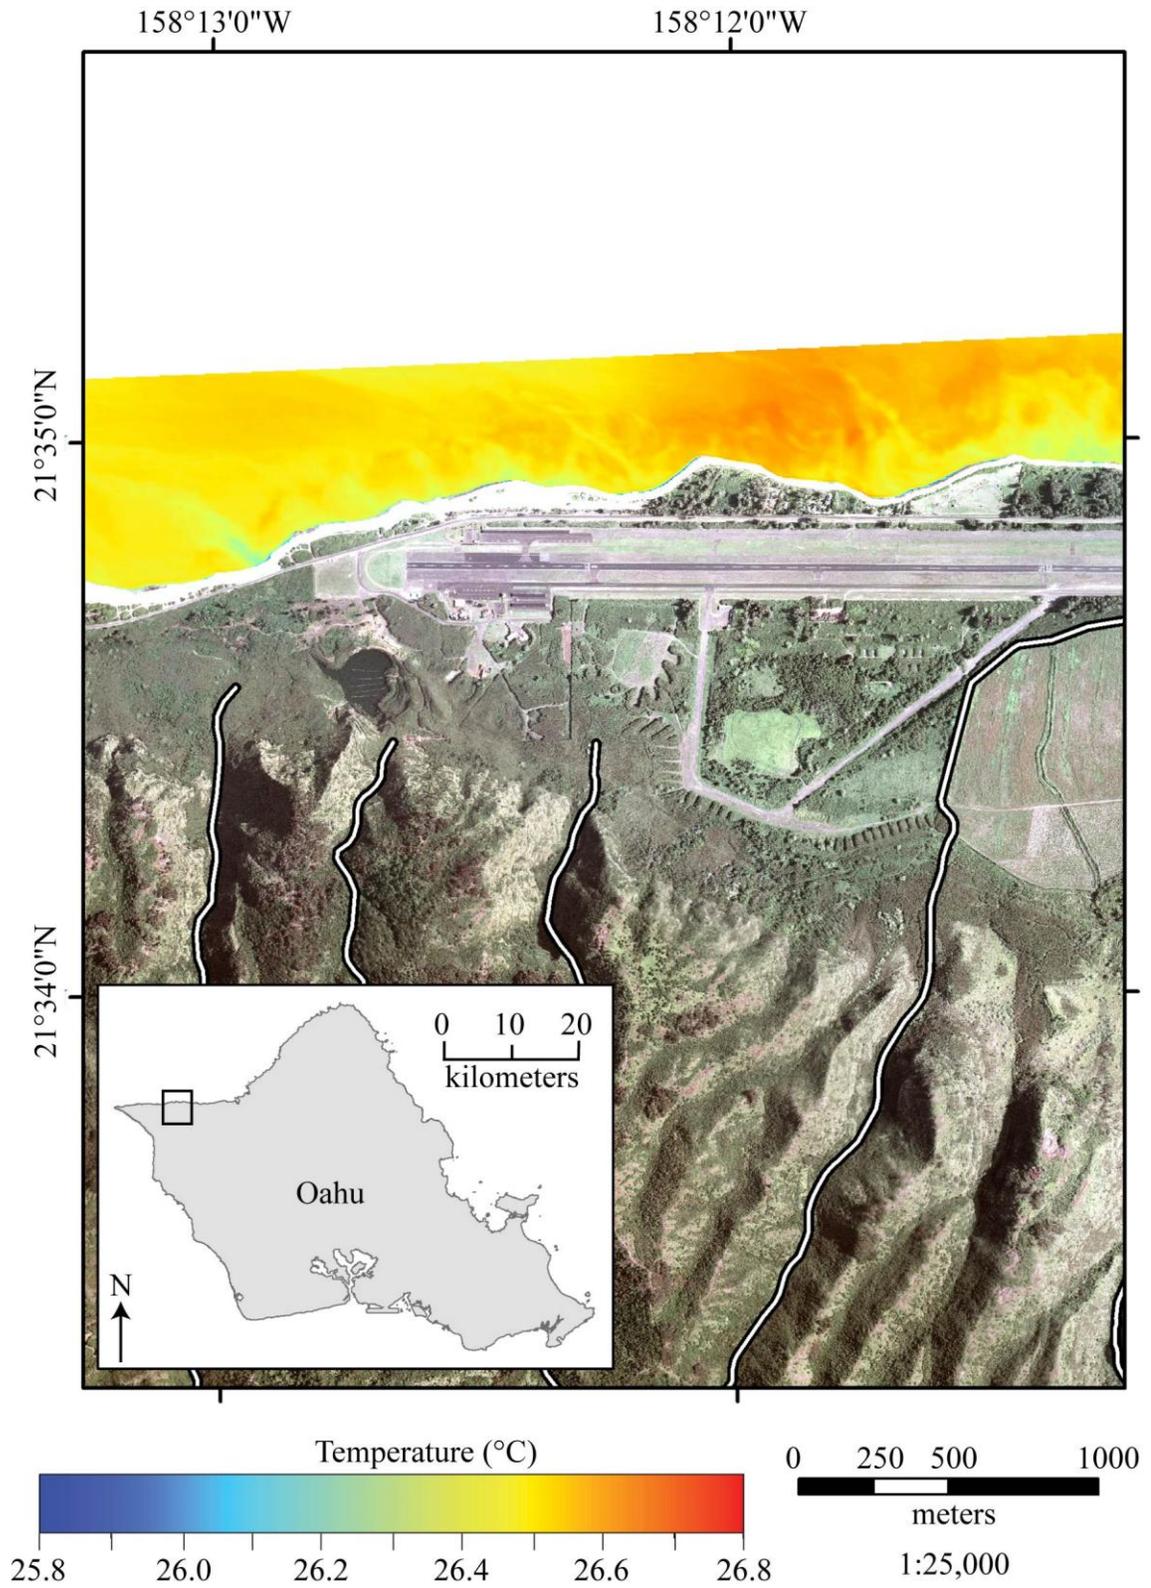

Panel 40: Kaena Point 22 July 2009 at 00:30-00:33 a.m., HST. Honolulu tide was +0.05 m MLLW.

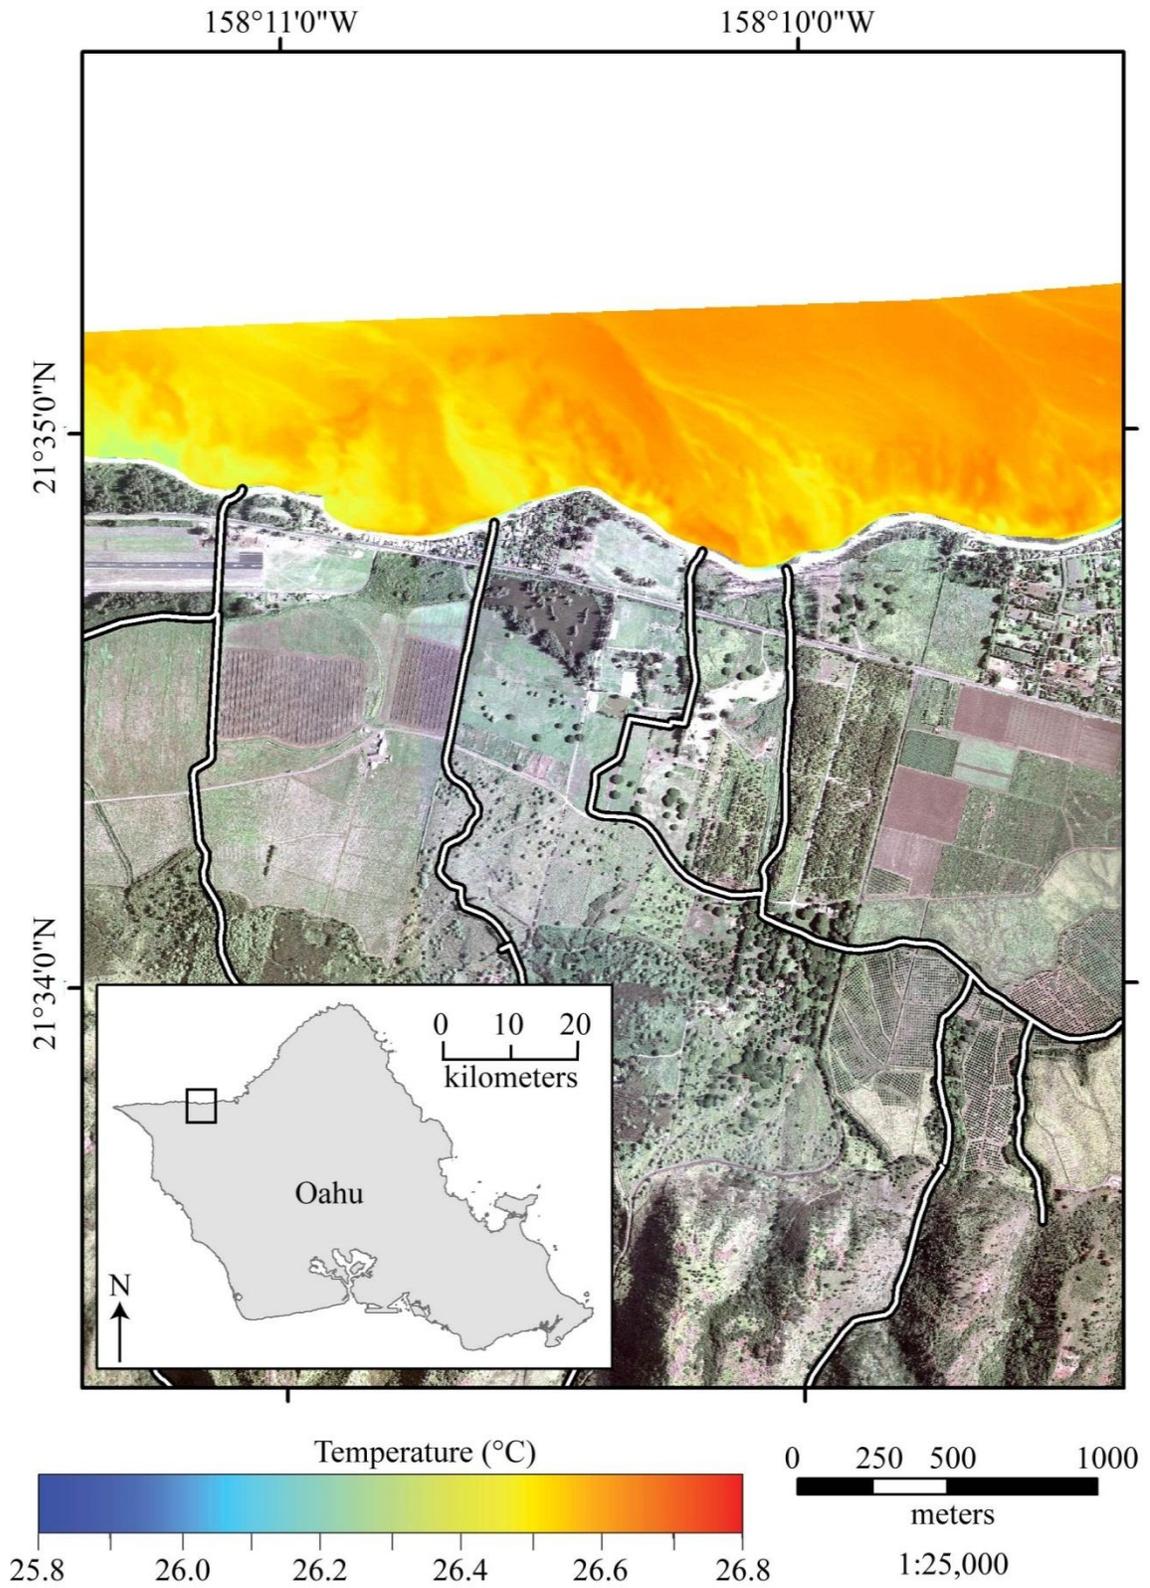

Panel 41: Kaena Point from 22 July 2009 at 00:36-00:43 a.m., HST. Honolulu tide was +0.05 to +0.06 m MLLW.

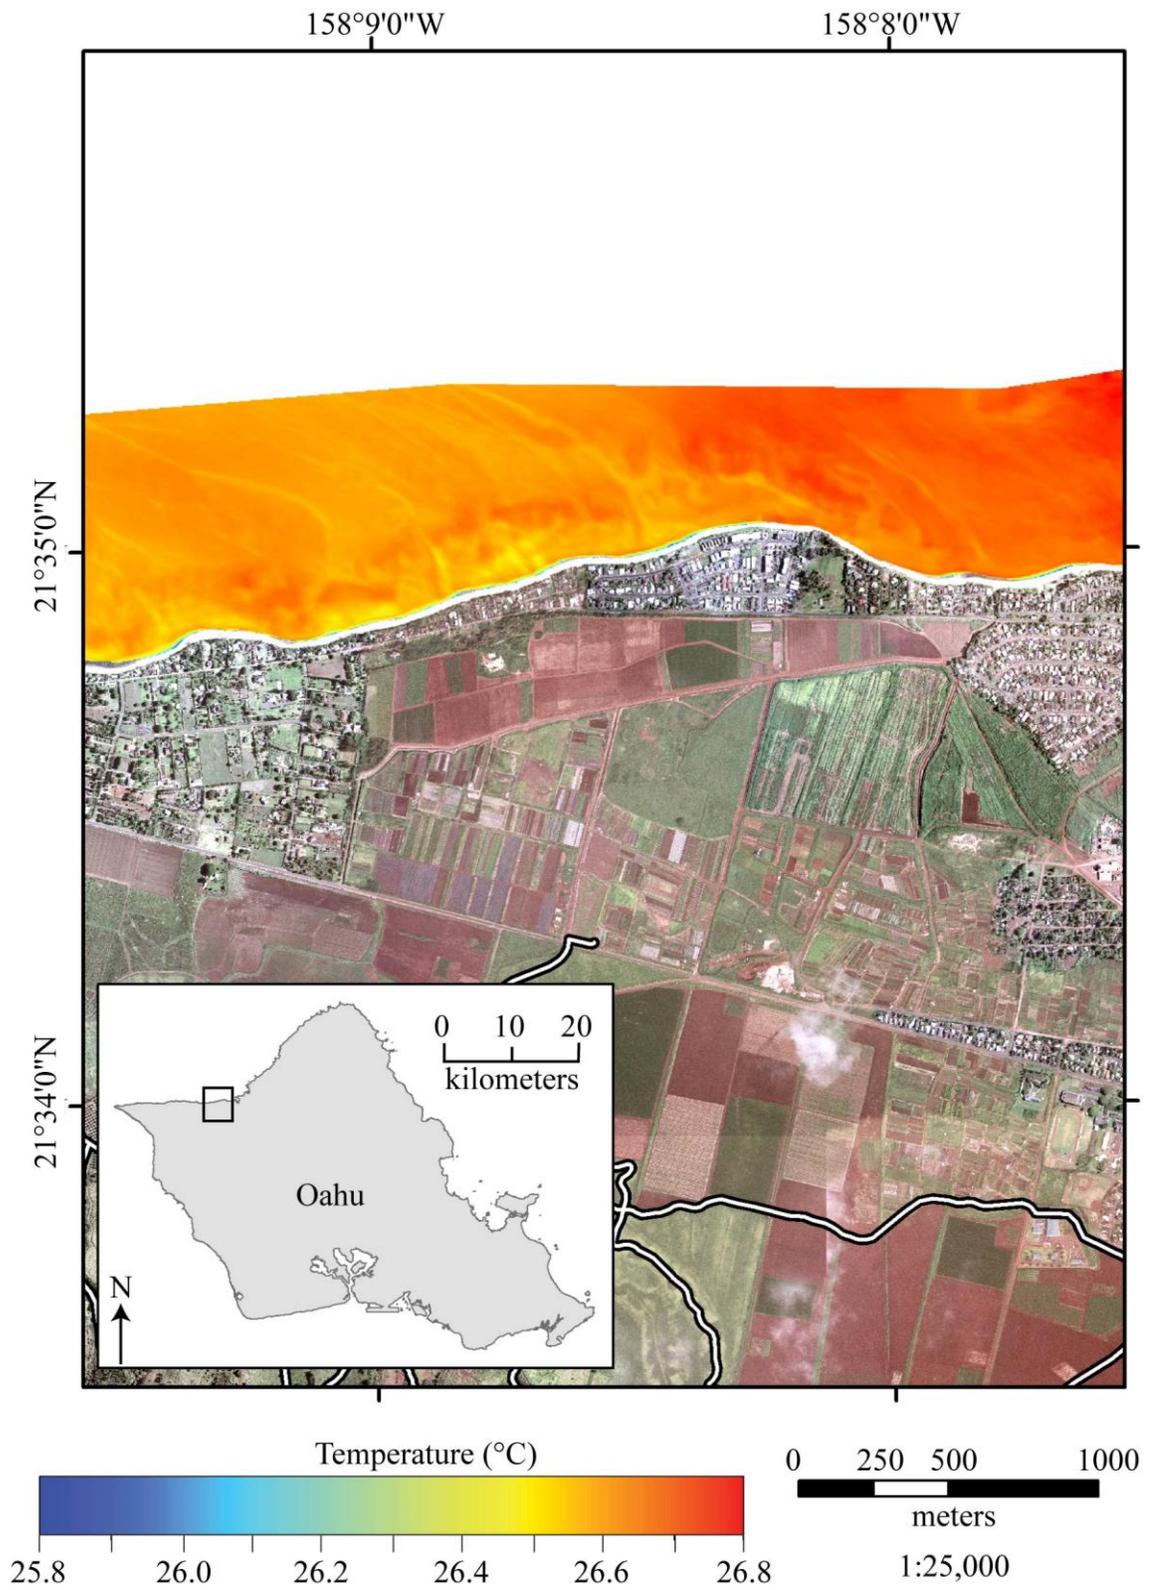

Panel 42: Kaena Point from 22 July 2009 at 00:36-00:43 a.m., HST. Honolulu tide was +0.05 to +0.06 m MLLW.

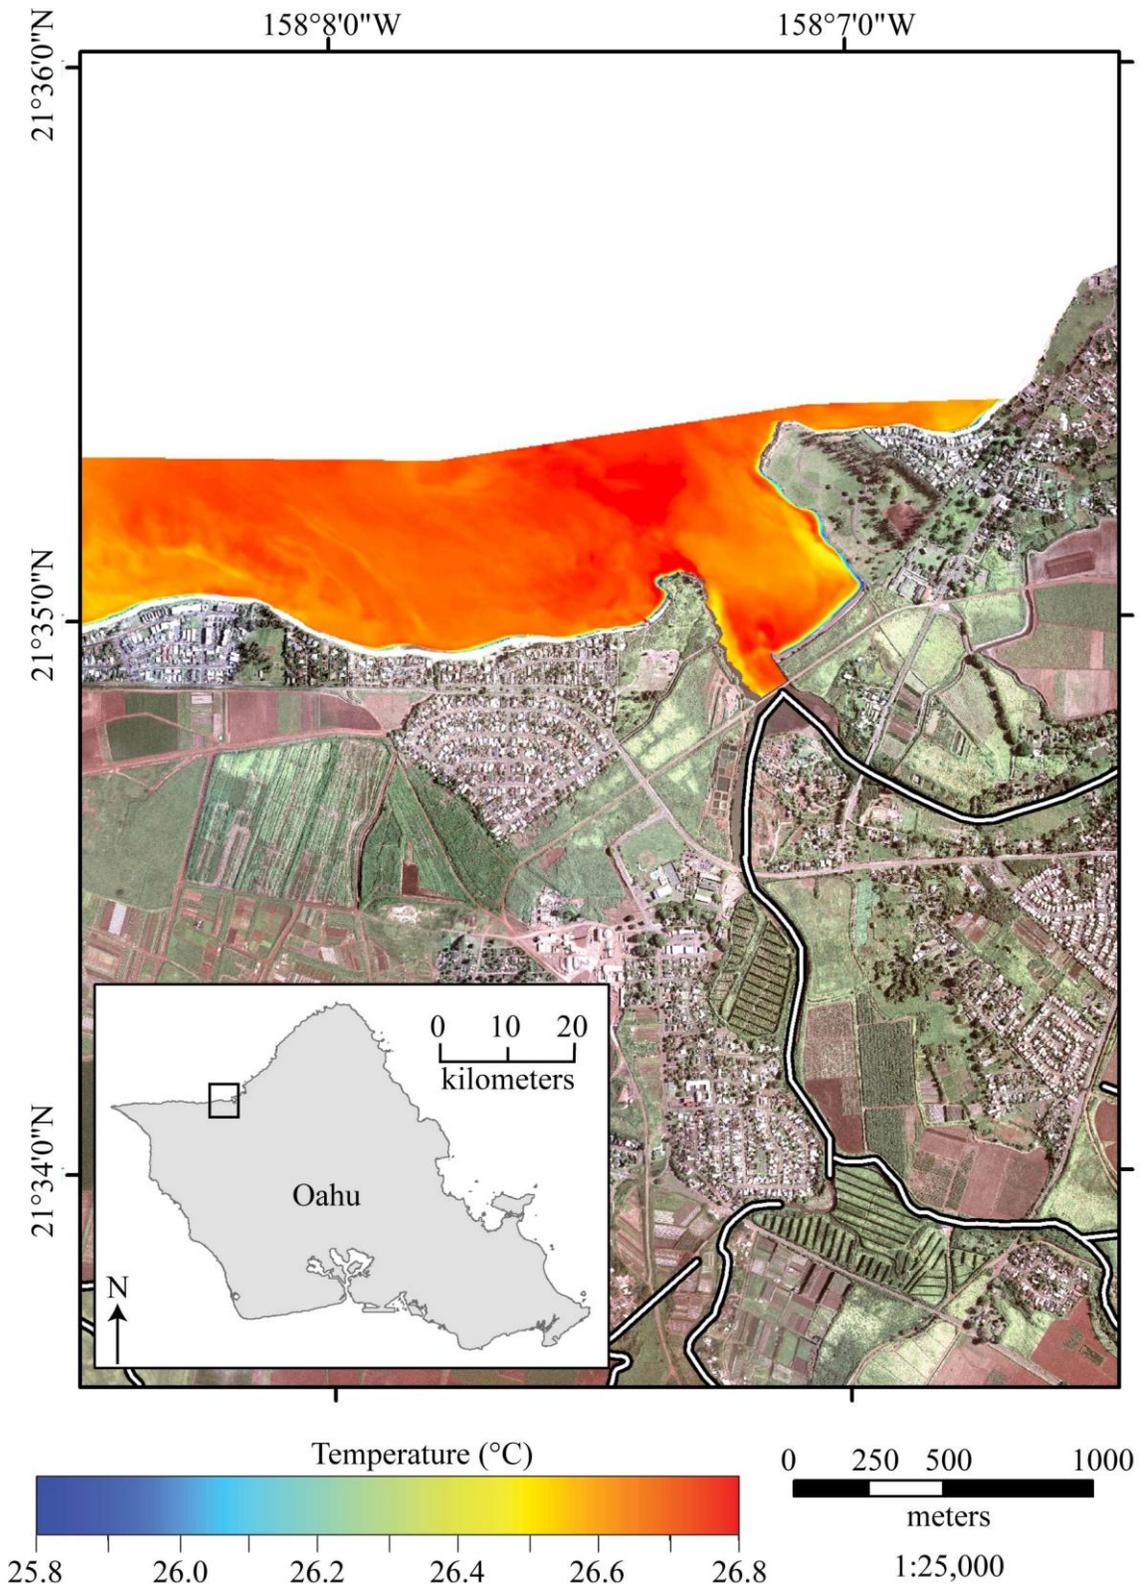

Panel 43: Dillingham Airfield from 22 July 2009 at 00:36-00:43 a.m., HST. Honolulu tide was +0.05 to +0.06 m MLLW.

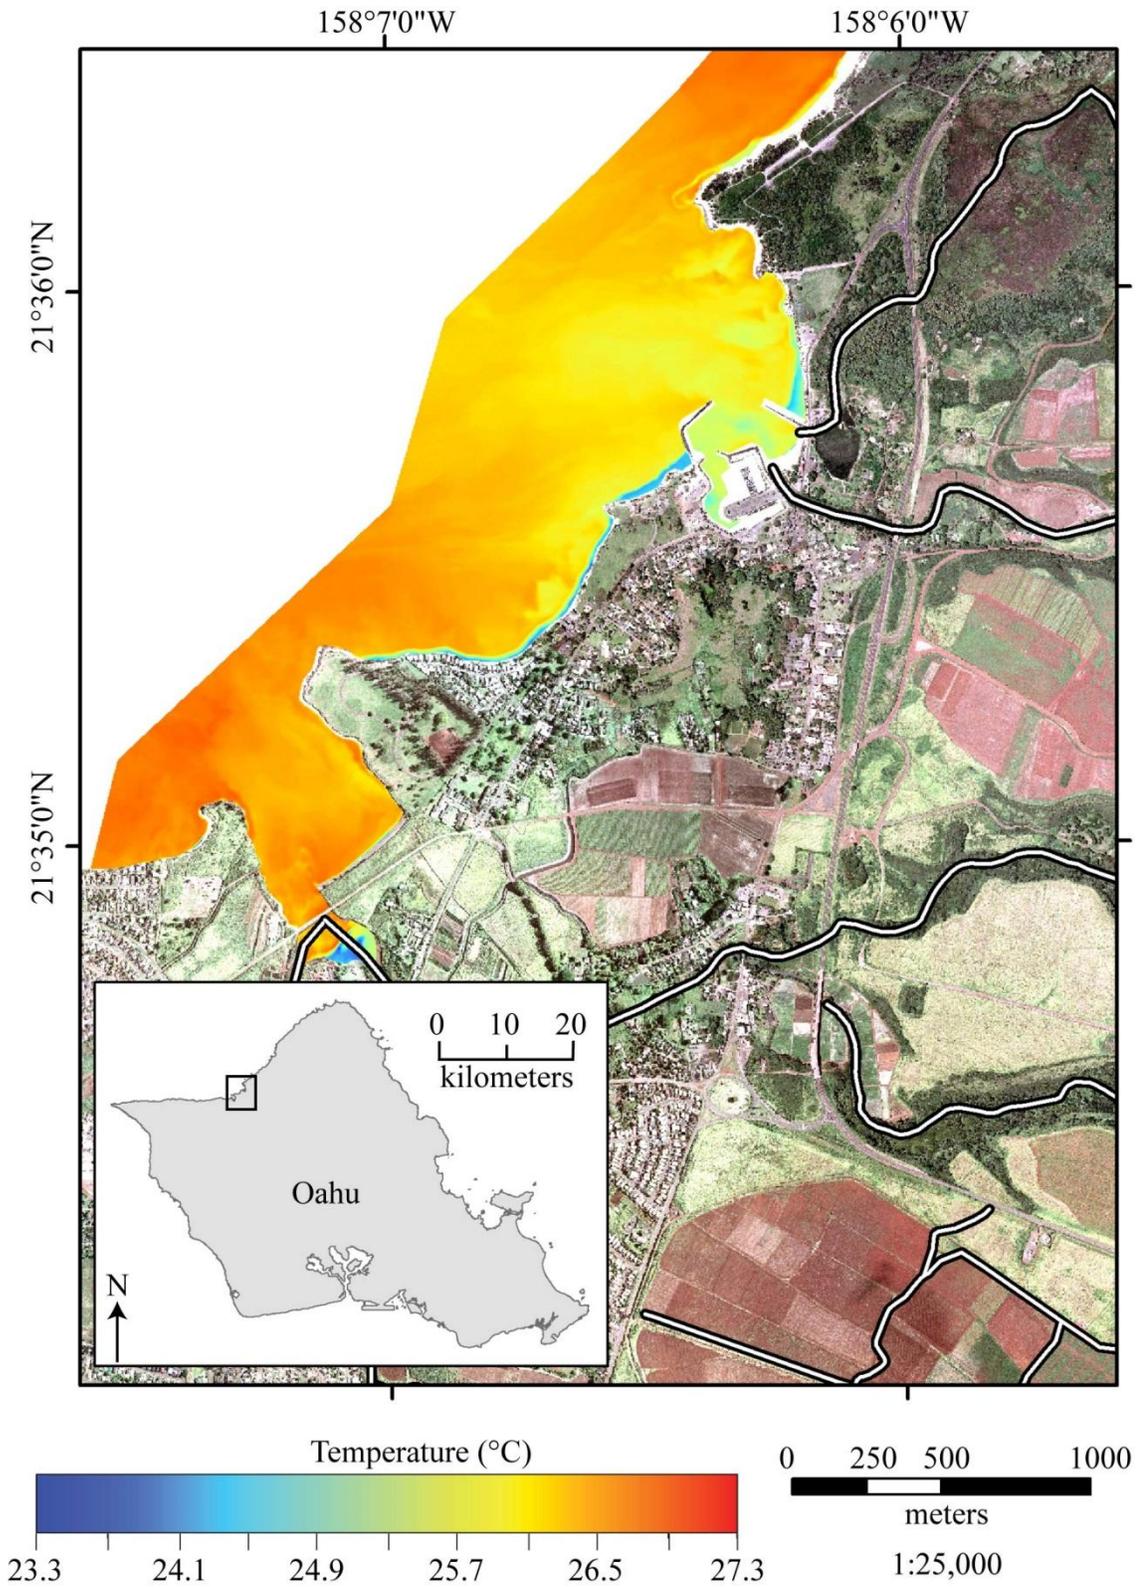

Panel 44: Dillingham Airfield from 22 July 2009 at 00:36-00:43 a.m., HST. Honolulu tide was +0.05 to +0.06 m MLLW.

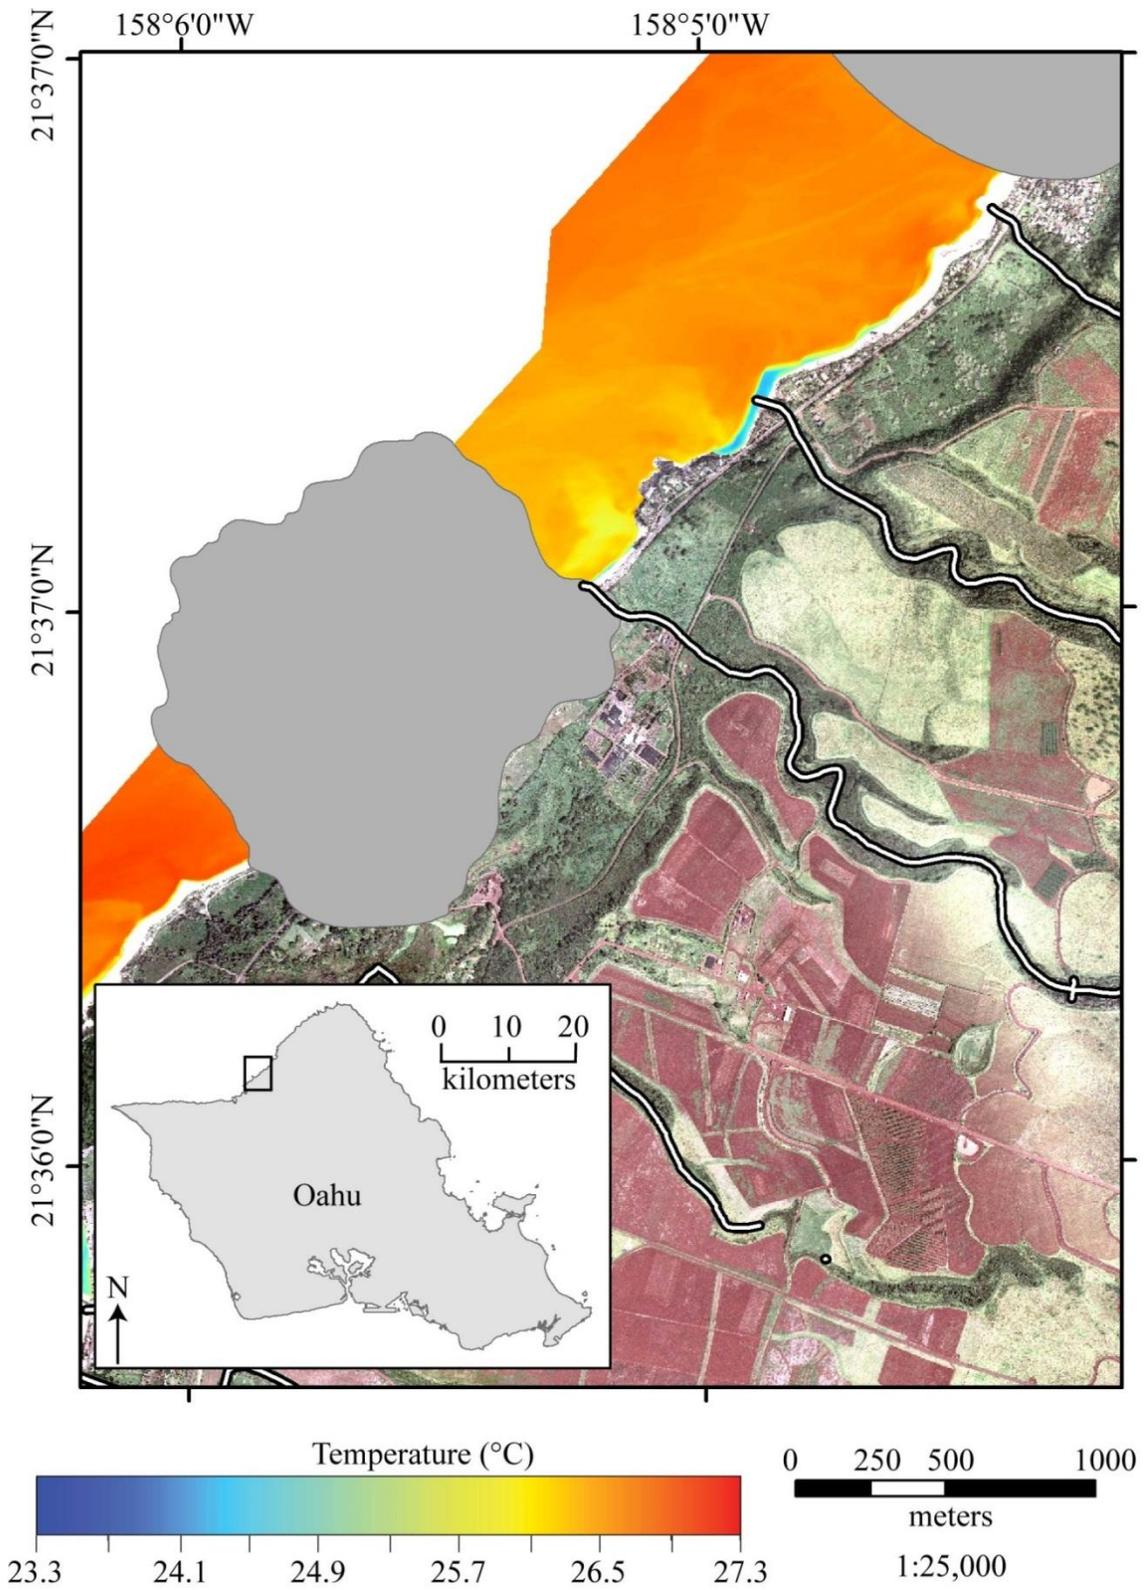

Panel 45: Mokuleia and Waialua from 22 July 2009 at 00:36-00:43 a.m., HST. Honolulu tide was +0.05 to +0.06 m MLLW.

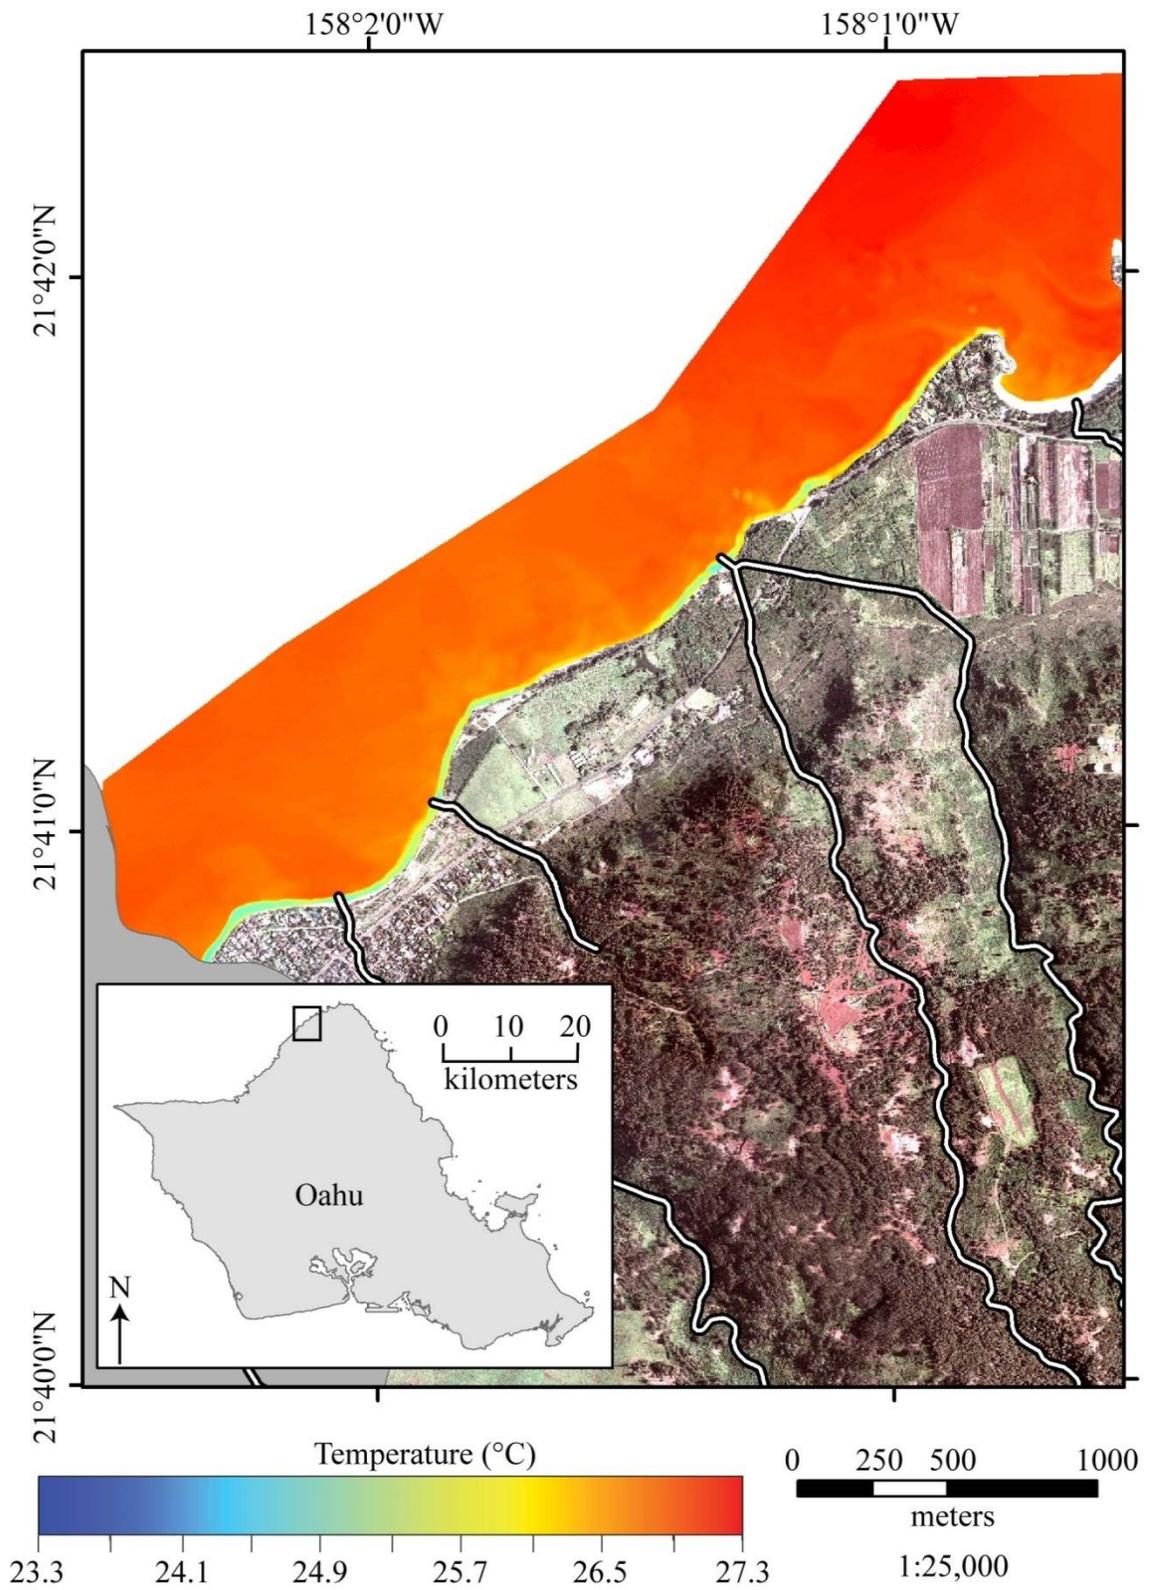

Panel 46: Kalaka Bay and Haleiwa from 22 July 2009 at 00:36-00:43 a.m., HST. Honolulu tide was +0.05 to +0.06 m MLLW.

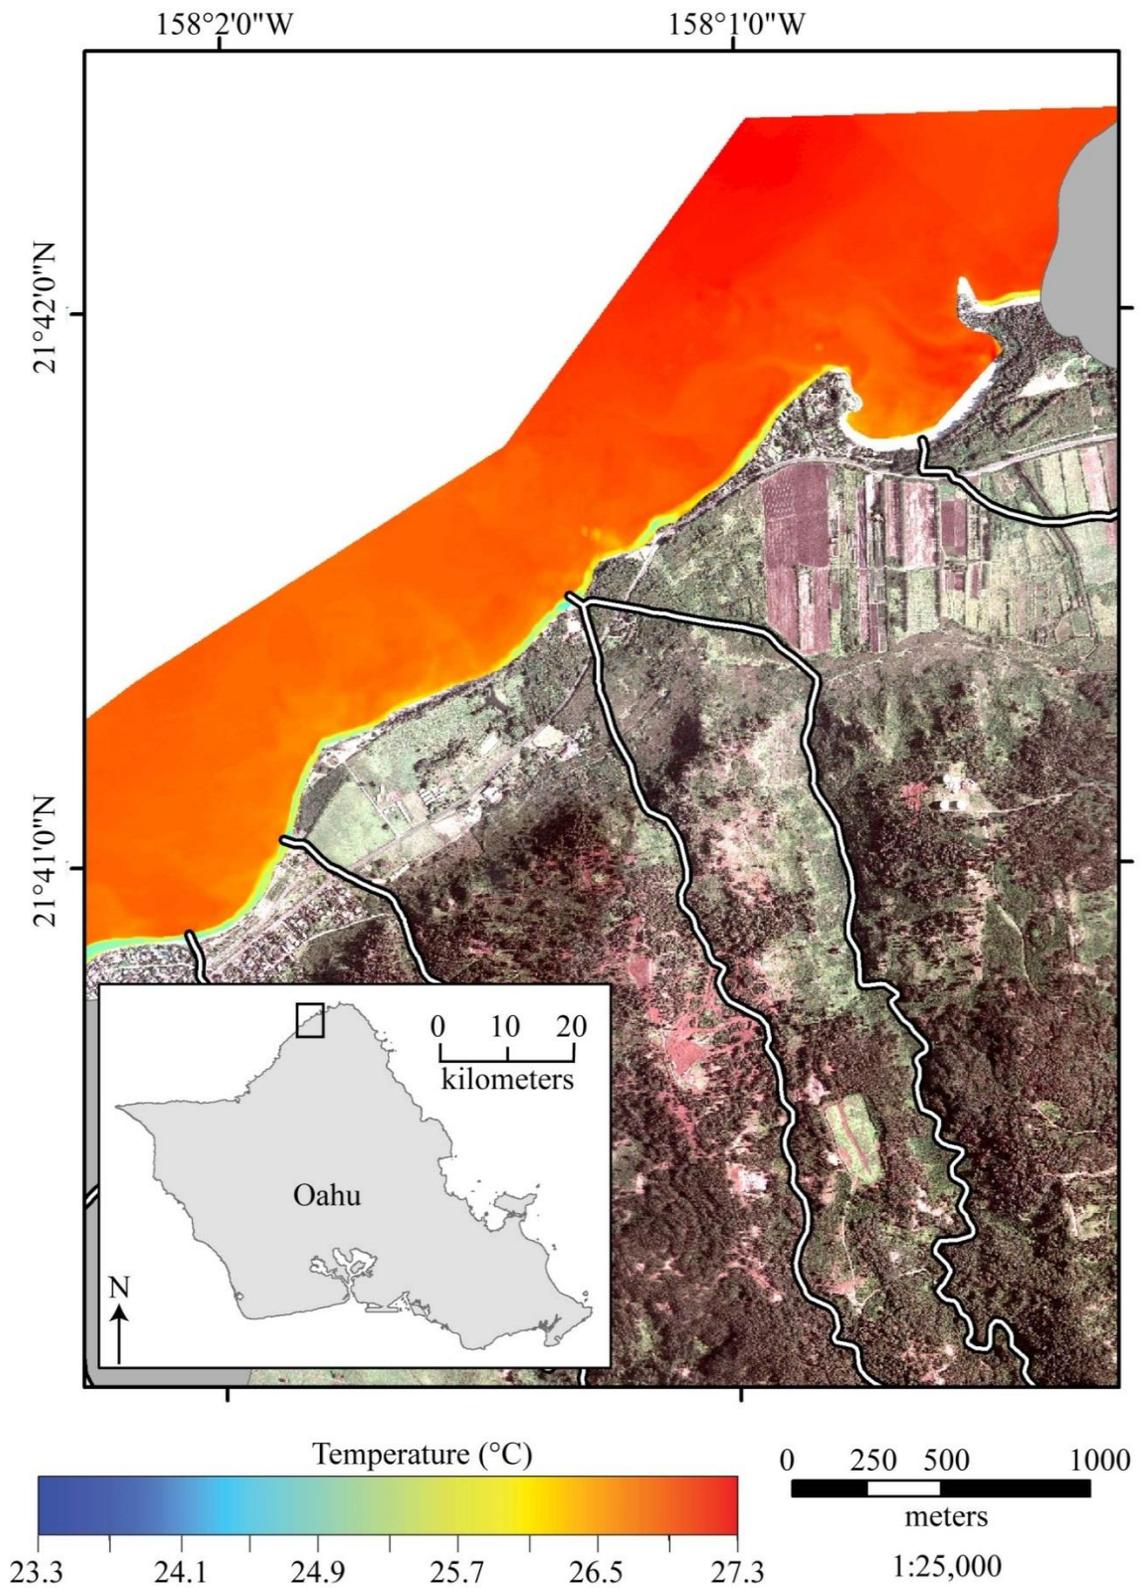

Panel 47: Kalaka and Waialua Bays near Haleiwa from 22 July 2009 at 00:50-00:57 a.m., HST. Honolulu tide was +0.07 to +0.08 m MLLW.

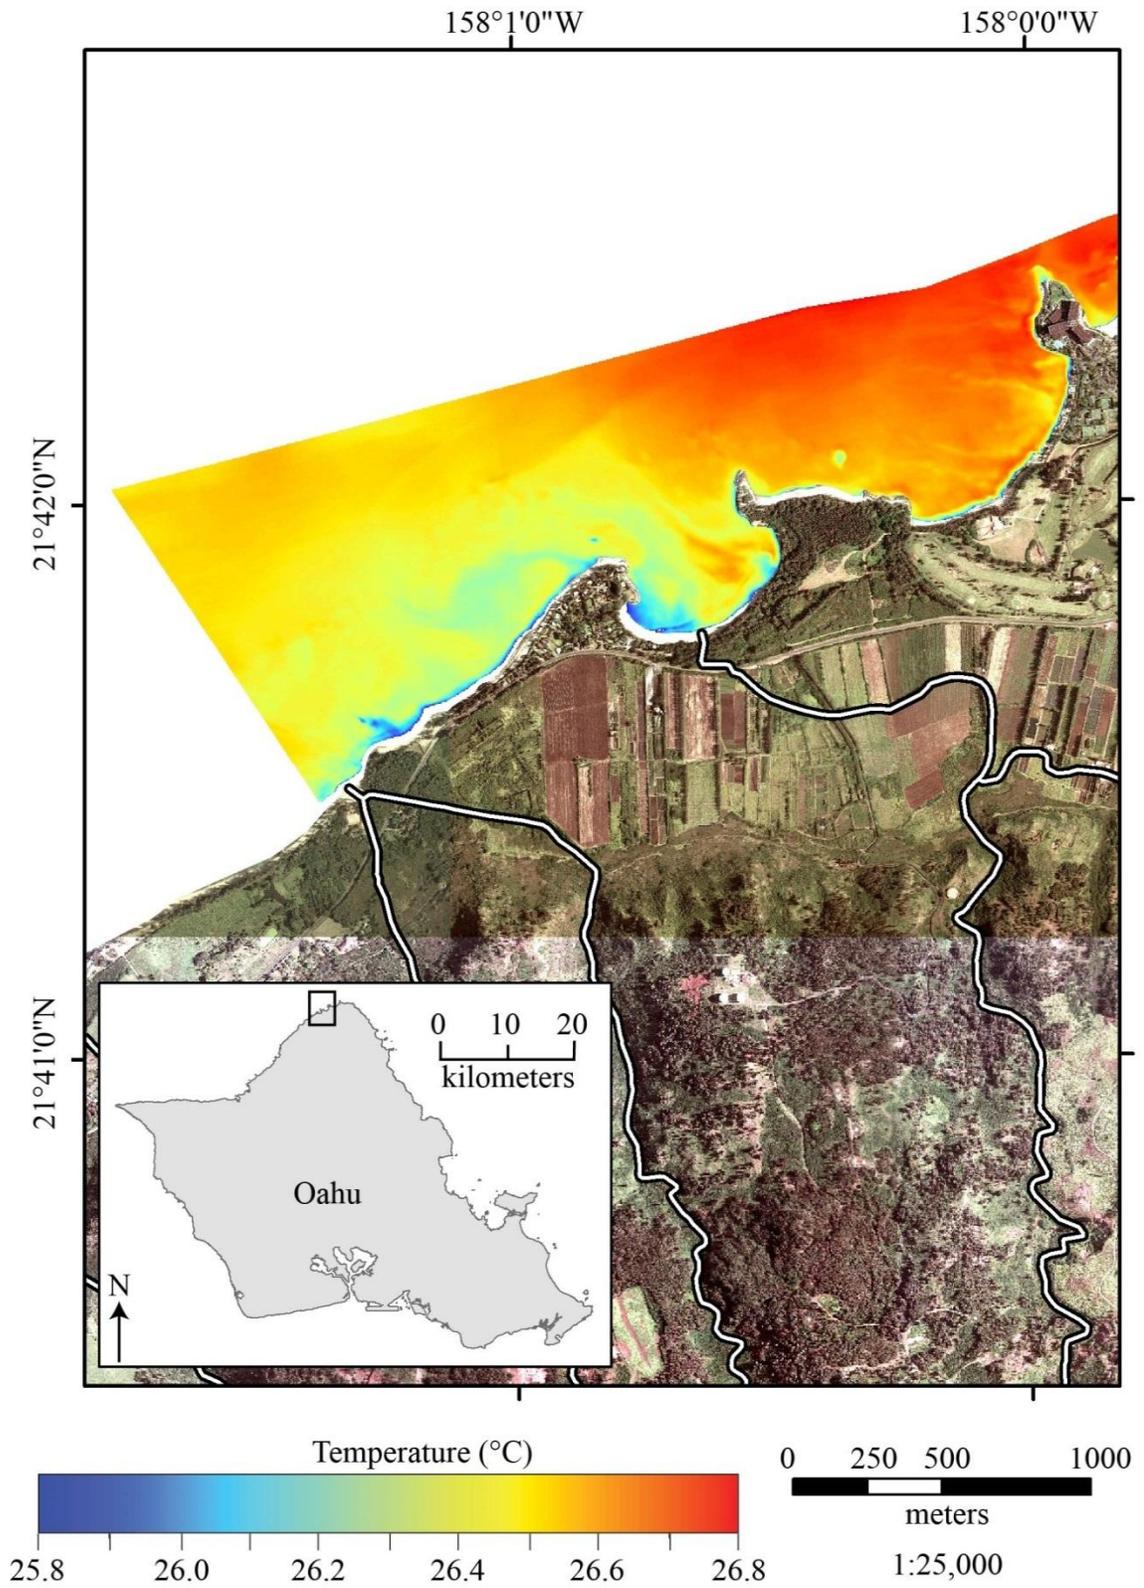

Panel 48: Northeast of Haleiwa from 22 July 2009 at 00:50-00:57 a.m., HST. Honolulu tide was +0.07 to +0.08 m MLLW.

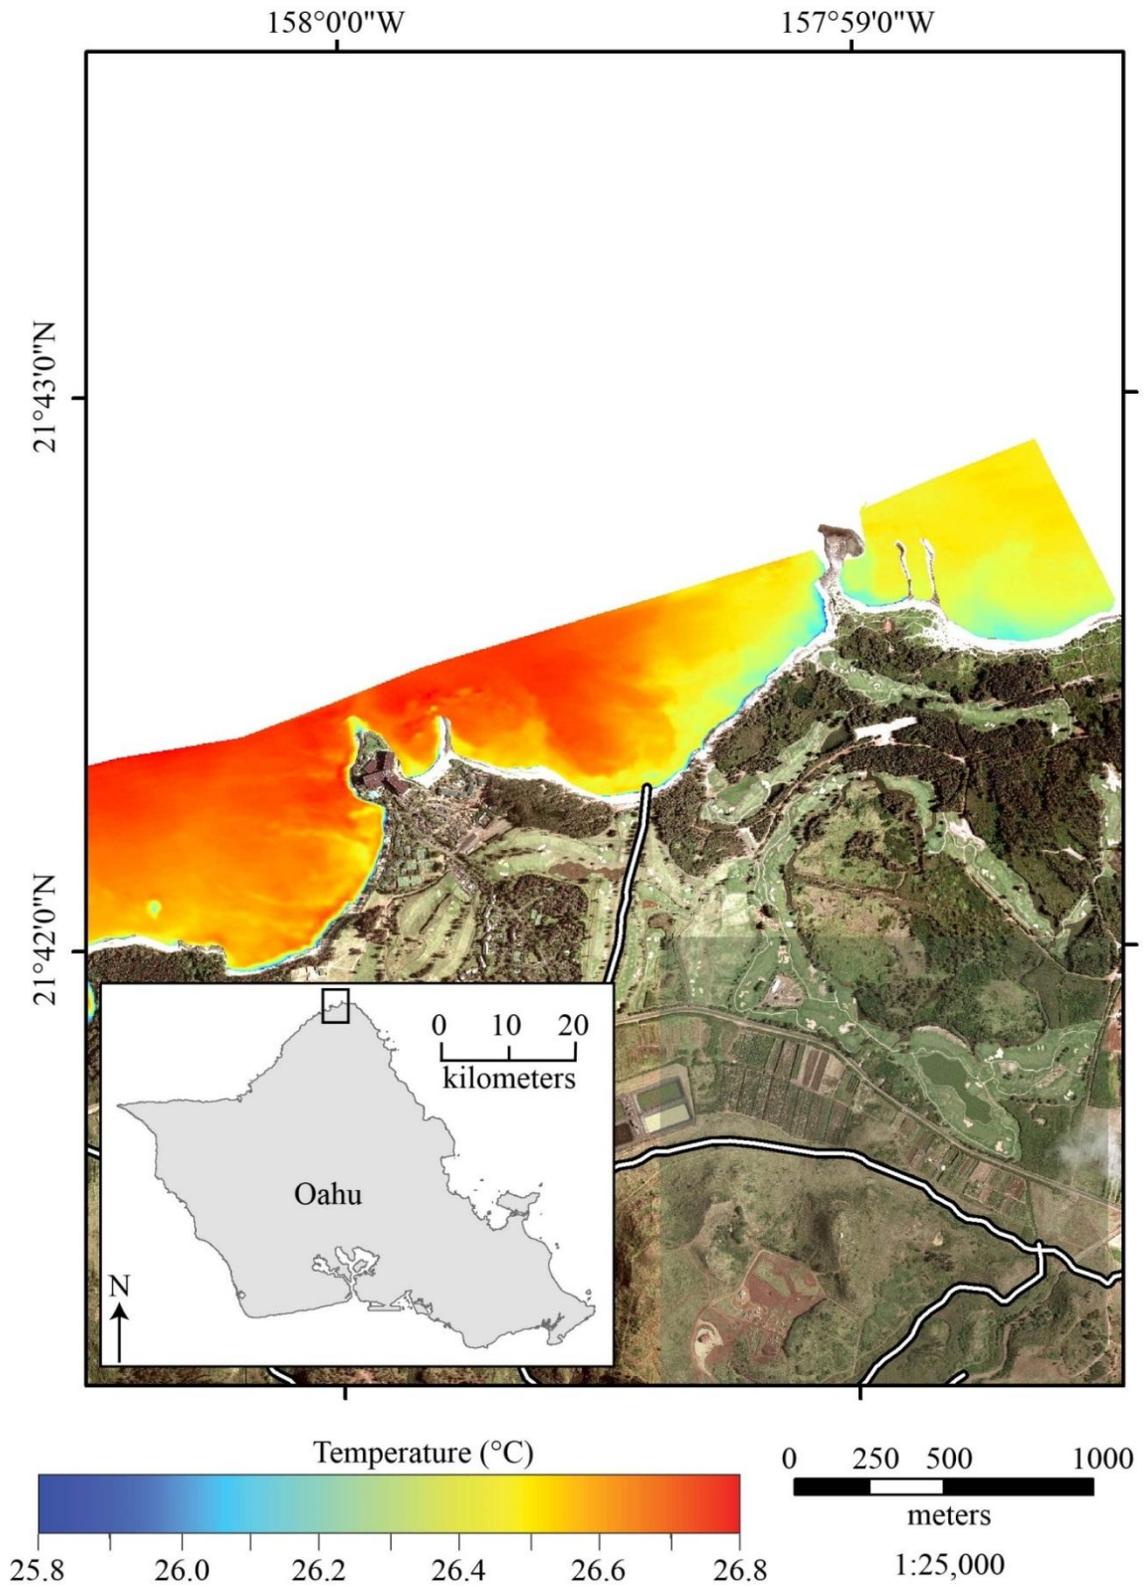

Panel 49: Southwest of Kawela Bay from 22 July 2009 at 00:50-00:57 a.m., HST. Honolulu tide was +0.07 to +0.08 m MLLW.

Panel 50: Southwest of Kawela Bay from 22 July 2009 at 00:50-00:57 a.m., HST. Honolulu tide was +0.07 to +0.08 m MLLW.

Panel 51: Kawela Bay from 22 July 2009 at 01:04-01:08 a.m., HST. Honolulu tide was +0.09 m MLLW.

Panel 52: Kawela Bay from 22 July 2009 at 01:04-01:08 a.m., HST. Honolulu tide was +0.09 m MLLW.

APPENDIX II. DATA

All raw data for analyses presented throughout the dissertation are presented in this appendix. Data include specific nutrient analyses, radon time-series measurements, radon surveys of surface waters, radon surveys of the water column, water quality data, wind-speed data, water-level data-logger data, global positioning system data, conductivity-temperature-depth data, stable isotope analyses of hydrogen and oxygen in water, stable isotope analyses of nitrogen and oxygen of dissolved nitrate, and chlorofluorocarbon data.

All specific nutrient data were analyzed at the University of Washington Oceanography Technical Services using a *Technicon Model AAI*. Data are reported per batch in chronological order.

All radon data tables are tabulated as two separate tables for each RAD-7 deployment. The first table contains RAD-7 raw data through window counts. The second table for each RAD-7 contains the remaining raw data. For all radon data tables, (eff) is efficiency, (Test #) is test number, (Yr) is year, (Mon) is month, (Hr) is hour, (Min) is minute, (Tot Cnt) is total counts, (Win) is window, (High Vol) is high voltage in units of volts, (HV duty) is a duty cycle with typical values of 10-20%, (Temp) is the temperature of the detector in Celsius, (R Hum) is % relative humidity of the sampled air, (Leak Curr) is leakage current and ranges from 0-255 mA but should be below 20 mA, (Batt Vol) is battery voltage in units of volts, (Pump Curr) is pump current in mA, (Flags Byte), which indicate individual settings, The measured activity concentration (Activity Con) is reported in units of bequerrels per cubic meter, (Error 2 sigma) is the error in bequerrels per cubic meter on the analysis, and (Units byte) indicates RAD-7 setting information.

All YSI (water quality) data are tabulated in separate tables, one per RAD-7 deployment. For all YSI data, temperature (T) is in Celsius, specific conductivity (SpCond) is in millisemens per centimeter °C, Salinity is (Sal), (DOsat) is dissolved oxygen saturation in percent, (DO) is dissolved oxygen in milligrams per liter, depth is in meters, chlorophyll (Chl) is in units of micrograms per liter, and oxidation reduction potential (ORP) is in units of millivolts. The XLM-600 YSI did not record chlorophyll

or oxidation reduction potential. These columns contain (N/A) for not applicable. The 6920 V2 YSI recorded all water quality parameters.

All wind speed data were from Honolulu International Airport weather station #911820, NCDC #22521 located at 21.238°N; 157.943°W. Data are reported at an hourly (or less) frequency.

For all water-level data-logger data, (GW Impacted Layer (cm)) is groundwater impacted layer. Air space is always negative because the zero-level of the water-level data-logger was set to the bottom of the actual logging device.

The water head reported for the temperature-conductivity-depth data reflects actual water depth. (Temp) is measured water temperature and (SpCond) is specific conductivity.

In some global positioning survey (GPS) logs for surface and depth profiling surveys, the GPS either lost power connection or only intermittently recorded data. Blank cells in GPS tables reflect these two circumstances.

Table AII.12: West Loch Platform B water-level data-logger data. The groundwater impacted layer is based on a thickness of 40 cm at 1128 on 7 January 2011 which corresponds to a similar tide at 1900 on 2 January 2010. An alternative modeled groundwater impacted layer of 143 cm requires addition of 103 cm to the groundwater impacted layer.

Table AII.12: (Continued) West Loch Platform B water-level data-logger data. The groundwater impacted layer is based on a thickness of 40 cm at 1128 on 7 January 2011 which corresponds to a similar tide at 1900 on 2 January 2010. An alternative modeled groundwater impacted layer of 143 cm requires addition of 103 cm to the groundwater impacted layer.

Table AII.12: (Continued) West Loch Platform B water-level data-logger data. The groundwater impacted layer is based on a thickness of 40 cm at 1128 on 7 January 2011 which corresponds to a similar tide at 1900 on 2 January 2010. An alternative modeled groundwater impacted layer of 143 cm requires addition of 103 cm to the groundwater impacted layer.

Table AII.24: East Loch Platform B water-level data-logger data. The groundwater impacted layer is based on a thickness of 40 cm at 1440 on 5 January 2011 which corresponds to a similar tide at 1300 on 5 January 2010. An alternative modeled groundwater impacted layer of 140 cm requires addition of 100 cm to the groundwater impacted layer.

1/4/10 16:55	-98.07	40.18	1/4/10 19:45	-84.33	53.92

Table AII.24: (Continued) East Loch Platform B water-level data-logger data. The groundwater impacted layer is based on a thickness of 40 cm at 1440 on 5 January 2011 which corresponds to a similar tide at 1300 on 5 January 2010. An alternative modeled groundwater impacted layer of 140 cm requires addition of 100 cm to the groundwater impacted layer.

Table AII.36: Middle Loch Platform B water-level data-logger data. The groundwater impacted layer is based on a thickness of 40 cm at 1236 on 19 January 2011 which corresponds to a similar tide at 2135 on 8 January 2010. An alternative groundwater impacted layer of 140 cm requires addition of 100 cm to the groundwater impacted layer.

Table AII.36: (Continued) Middle Loch Platform B water-level data-logger data. The groundwater impacted layer is based on a thickness of 40 cm at 1236 on 19 January 2011 which corresponds to a similar tide at 2135 on 8 January 2010. An alternative groundwater impacted layer of 140 cm requires addition of 100 cm to the groundwater impacted layer.

Table AII.41: (Continued) Inlet Platform water-level data-logger data.
The groundwater impacted layer is based on a thickness of 40 cm at 1236
on 19 January 2011.

1.26	14:40	25.81	51.15	33.57	8.11	128.9	2.9	100.8	6.77

Table AII.47: Rainbow Bay D-Dock Platform 1 water-level data-logger data. The groundwater impacted layer is based on a thickness of 40 cm at 1440 on 5 January 2011 which corresponds to a similar tide at 1942 on 26 February 2010. An alternative groundwater-impacted layer of 140 cm requires addition of 100 cm to the groundwater-impacted layer.

Table AII.47: (Continued) Rainbow Bay D-Dock Platform 1 water-level data-logger data. The groundwater impacted layer is based on a thickness of 40 cm at 1440 on 5 January 2011 which corresponds to a similar tide at 1942 on 26 February 2010. An alternative groundwater-impacted layer of 140 cm requires addition of 100 cm to the groundwater-impacted layer.

Table AII.47: (Continued) Rainbow Bay D-Dock Platform 1 water-level data-logger data. The groundwater impacted layer is based on a thickness of 40 cm at 1440 on 5 January 2011 which corresponds to a similar tide at 1942 on 26 February 2010. An alternative groundwater-impacted layer of 140 cm requires addition of 100 cm to the groundwater-impacted layer.

Table AII.51: (Continued) Rainbow Bay D-Dock Platform 2
 wind speed data from Honolulu International United States Air
 Force #911820, NCDC #22521 weather station located at
 21.238°N; 157.943°W.

Date yyyymmdd	Time hh:mm	Wind Speed m/s	Date yyyymmdd	Time hh:mm	Wind Speed m/s
20100302	08:53	7.70	20100302	10:53	7.20
20100302	09:53	5.70			

Table AII.52: Rainbow Bay D-Dock Platform 2 depth profile collected on 5 January 2011 using the YSI 6600 V2-4.

Depth m	Time hh:mm	Temp °C	SpCond mS/cm	Sal	pH	ORP	Chl µg/L	DO %	DO mg
0.040	15:16	26.10	50.47	33.06	8.11	127.3	2.2	102.4	6.88
0.450	15:17	26.01	50.81	33.31	8.11	127.6	2.3	101.6	6.83
1.141	15:17	25.87	51.13	33.55	8.12	127.9	3.1	101.2	6.81
1.355	15:18	25.87	50.94	33.41	8.12	127.8	7.3	100.6	6.77

Table AII.53: Rainbow Bay D-Dock Platform 2 water-level data-logger data. The groundwater impacted layer is based on a thickness of 40 cm at 1518 on 5 January 2011 which corresponds to a similar tide at 1810 on 27 February 2010. An alternative groundwater impacted layer of 140 cm requires addition of 100 cm to the groundwater impacted layer.

Table AII.53: (Continued) Rainbow Bay D-Dock Platform 2 water-level data-logger data. The groundwater impacted layer is based on a thickness of 40 cm at 1518 on 5 January 2011 which corresponds to a similar tide at 1810 on 27 February 2010. An alternative groundwater impacted layer of 140 cm requires addition of 100 cm to the groundwater impacted layer.
