Materials and Methods

<u>Data</u>

     Five datasets are utilized in this study: satellite altimetry sea surface height data, Argo profiling float temperature and salinity (T/S) data, WOA05 climatological T/S data, Arabian Sea Experiment mooring data, and Kuroshio Extension System Study (KESS) mooring data. All these datasets are publicly downloadable from Internet.

     For the altimetry SSH data, we use the delayed-time product produced by AVISO (available at: http://www.aviso.oceanobs.com). The AVISO dataset consists of the globally gridded sea level anomaly (SLA) field from multiple simultaneously operating satellites, with a 0.25° ×0.25° spatial resolution. The time-span is from Oct 1992 to Jan 2010, with a 7-day temporal resolution. The SLA field is defined to be the residuals relative to the 7-year (i.e., 1993-1999) mean.

     The Argo profiling float data is provided by China Argo Real-time Data Center (http://www.argo.gov.cn/argo-eng/index.asp). The dataset consists of about 600,000 T/S profiles in the upper 2,000 m between 1996 and 2010, with time and location of each profile recorded. These T/S data have been subject to real-time quality control (*S1*). From the T/S profiles, the potential density ρ profile relative to the sea surface (density for short hereafter) can be readily calculated.

     The World Ocean Atlas 2005 data is provided by National Oceanographic Data Center (http://www.nodc.noaa.gov/OC5/WOA05/pr_woa05.html), and the objectively analyzed 1° gridded climatological T/S field is used here. We mainly use the seasonal mean field, and also compute the potential density from temperature and salinity field relative to the sea surface.

     The Arabian Sea Experiment mooring data is provided by Woods Hole Oceanographic Institution (http://uop.whoi.edu/archives/arabiansea/arabiansea.html). The mooring was located at 30.5°N, 61.5°E and collected vertical T/S profiles during October 1994 to October 1995.

     The Kuroshio Extension System Study (KESS) project provides 2 years of subsurface mooring data (available at: http://uskess.org/data_public.html). The mooring system was deployed in the Kuroshio Extension region near 34°N 146°E during May 2004 to May 2006.

<u>Reconstruct</u> <u>Eddy</u> <u>Density</u> <u>Field</u>

     Reconstruction of the eddy density field is divided into three steps: First, identify eddies from the weekly altimetry SLA maps, and determine the SLA value at the eddy's center and their radius. Then, use the available Argo density profiles to composite the normalized, three-dimensional (3-D) structure of the eddy's density anomaly field. Finally, combine the altimetry SLA signal and the composite eddy density structure to reconstruct the density field for individual eddies.

66   In order to identify the eddies from altimetry, we search localized extremes of SLA

67 first. If an extreme point is surrounded by closed contours of Okubo-Weiss parameter W

68 $= -2 \times 10^{-12}$ s^{-1} (S2, S3), this point is then recognized as an eddy center. The Okubo-

69 Weiss parameter is given by (S4, S5):

70
$$W = 4(u_x^2 + v_x u_y) \tag{1}$$

71 where the horizontal velocities are calculated by geostrophic balance $u = -(g/f)\eta_y$ and v

72 $= (g/f)\eta_x$, (η is SLA, g is gravity acceleration), and the subscripts x and y represent the

73 zonal and meridional spatial derivatives, respectively. The radius of the eddy R_0 is given

74 by the equal-area circle of the closed W contour surrounding the eddy center (S6), and the

75 SLA at the eddy's center η_0 is directly evaluated from the altimetry maps.

76   To derive the vertical structures of the mesoscale eddies, we follow the composite

77 analysis approach of (S7) based on the Argo profiling float data. Specifically, after

78 constructing its density structures from the T/S profiles, the eddy's density anomaly

79 profile $\rho_e(z)$ is calculated relative to the local seasonal mean density profile from the

80 WOA climatology. The Argo float-derived density anomaly profile is then projected onto

81 the eddy-center coordinate, with the distance to the eddy center r as the horizontal

82 ordinate and depth z as the vertical ordinate. Considering the eddy structure variations in

83 different regions, the composition is conducted in a 30°latitude×30°longitude box. This

84 size of the region is big enough to ensure there are enough Argo profiles to perform the

85 composition, but small enough to avoid smearing out of eddy structures. The composite

86 density anomaly profile in a region is constructed by double normalization, with the

87 horizontal scale normalized by the eddy radius R_0 and the amplitude normalized by SLA

88 at the eddy center η_0:

89
$$\rho_n(r_n, z) = \eta_0^{-1} \cdot \rho_e(r/R_0, z) \tag{2}$$

90 where $r = (x^2 + y^2)^{1/2}$ is the distance to the eddy center, $r_n = r/R_0$ is the normalized

91 distance, and (x, y) are the zonal and meridional ordinates relative to the eddy center. Our

92 former study (S7) indicates that the variables (r_n, z) for the normalized density anomaly

93 field are functionally separable:

94
$$\rho_n(r_n; z) = R(r_n) \cdot H(z) \tag{3}$$

95 where $R(r_n)$ provides the radial structure and $H(z)$ the vertical structure. According to our

96 former study (S7), the radial structure of eddy can be described by a universal analytic

97 function: $R(r_n) = (1 - r_n^2/2)\exp(1 - r_n^2/2)$, and this function is used in our reconstruction

98 procedures. The vertical structures of mesoscale eddies obtained in the regional

99 composite analysis are recorded in a 1° x 1° global grid.

100   With the regional composite eddy structure and the radius R_0 and center SLA η_0 of

101 an eddy identified by altimetry, the density anomaly field of the individual eddy can be

102 reconstructed by $R(r_n)$ and $H(z)$ *specific* to the nearest grid point:

103
$$\rho_e(r, z) = \rho_e(r_n \cdot R_0, z) = \eta_0 \cdot R(r_n) \cdot H(z) = \eta(r) \cdot H(z) \tag{4}$$

104 where $\eta(r)$ is the radial structure of SLA. By adding the background seasonal density
105 profile $\bar{\rho}(x,y,z)$ to $\rho_e(r, z)$, the total density field $\rho(x,y,z)$ of the eddy is obtained. *All*
106 *mesoscale eddies have a universal structure in normalized stretching coordinate (S7)*,
107 however, the reconstructed density structure $\rho(x,y,z)$ is different for each individual
108 eddies.
109
110 <u>Validation of the Reconstruction Method</u>
111   Since the accuracy of the potential vorticity field is highly dependent on the
112 reconstructed density field, we use *in situ* mooring observations from three sites to
113 validate our reconstruction method.
114   The first mooring system is deployed at 60.6°N, 52.4°W in the Labrador Sea from
115 September 2007 to September 2009 (*S8*). This 2-year mooring measurements captured 12
116 warm-core eddies, and the detailed information of SLA at the eddy center, the radius of
117 eddy and the countercurrent isopycnal displacement is available in (*S8*). We first take a
118 warm-core eddy captured by the mooring at October 11 2008 as an example, with a
119 center SLA $\eta_0 = 0.081\ m$ and eddy radius $R_0 = 20\ km$. First, use the universal radial
120 structure of eddy to reconstruct its SLA distribution:

$$\eta(r) = \eta_0 \cdot \left[1 - \frac{1}{2} \left(\frac{r}{R_0} \right)^2 \right] \cdot \exp \left[1 - \frac{1}{2} \left(\frac{r}{R_0} \right)^2 \right] \tag{5}$$

122   Then, get the regional composite vertical structure of eddy $H(z)$ at the grid point
123 61°N, 52°W. The density structure of this eddy can be calculated by $\rho_e(r, z) = \eta(r)\ H(z)$.
124 Finally, combining the winter background density profile $\bar{\rho}(x,y,z)$ from WOA data, the
125 eddy density field is reconstructed by: $\rho(r,z) = \rho_e(r,z) + \bar{\rho}(x,y,z)$, as shown in Fig.1A in
126 the main text. Notice that with the mooring provides only the time series of density
127 profiles, the time has been transformed into distance by the horizontal propagation speed
128 (25.8 cm s^{-1}) of the eddy. The density structures of the other 11 warm-core eddies are
129 reconstructed in the same way. Figure 1C in the main text compares the observed and
130 reconstructed 27.7 kg m^{-3} isopycnal displacement at the eddy center as blue points.
131   The second mooring located at 15.5°N 61.5°E is from the Arabian Sea Experiment.
132 During its one-year deployment, two cold-core eddies and one warm-core eddy were
133 observed. The first cold-core eddy is observed on November 30 1994, and its density
134 field is reconstructed and compared with the *in situ* density section from the mooring as
135 an example of cold-core eddy in Fig.1B. The observed 26.0 kg m^{-3} isopycnal
136 displacement at the eddy center is 73.7 m and the corresponding reconstructed
137 displacement is 65.7 m. The other cold-core eddy and the warm-core eddy were observed
138 on August 30, and July 5, 1995, respectively. The observed and reconstructed 26.0 kg m^{-3}
139 isopycnal displacements of these three eddies are compared in Fig.1C as black squares.
140   The third mooring is from the KESS project, which used a subsurface profiler on the
141 moorings to observe temperature and salinity. There are a total of eight moorings (K1-

142   K8), but it seems that the profilers did not work well during strong eddy events. After

143   checking the records of the eight moorings, only two warm-core eddy observations can

144   be used to validate our reconstruction method. The first warm-core eddy was observed by

145   the K3 mooring at 146.9E 35.5N on March 15, 2006 and the second warm-core eddy by

146   the K4 mooring at 146.2E 35.2N on February 9, 2005. The reconstructed 27.4 kg m^{-3}

147   isopycnal displacements of these two eddies are compared with their observed values in

148   Fig.1C with red triangles.

149   The comparisons shown in Fig.1C indicate that the relative error of the

150   reconstructed density field is about 20% of the observed variance. It is important to

151   mention that our verification covers the low-, mid- and high-latitude regions in the

152   Pacific, Atlantic and Indian Oceans. It also involves both polarities of the mesoscale

153   eddies (unfortunately only two cold-cold eddies out of the 17 eddy samples are available

154   for validation). We believe the 20% relative error is sufficiently small that validates the

155   reconstruction method adopted in this study.

156

157   The Potential Vorticity Field

158   We estimate the potential vorticity (PV) q by following its definition:

159
$$q = \frac{(f+\omega)\rho_z}{\rho_0} \tag{6}$$

160   where ω is relative vorticity, ρ_z is vertical gradient of density, ρ_0 is mean density and f is

161   the Coriolis parameter. Following a fluid particle, q is conserved if the environment is

162   inviscid and adiabatic.

163   With ρ_z calculated from the reconstructed eddy density field, the only unknown

164   quantity in (6) is relative vorticity. To estimate the relative vorticity, we use the

165   reconstructed eddy density anomaly field $\rho_e(r,z) = \eta(r) H(z)$ to first compute the eddy

166   pressure anomaly field $p_e(r,z) = \eta(r) P(z)$ through hydrostatic balance with a reference

167   level at 2,000 m, where $P(z)$ is:

168
$$P(z) = -\int_{-2000}^{z} g \cdot H(z')dz' \tag{7}$$

169   and g is the gravity acceleration. Then we use the geostrophic balance to compute the

170   horizontal velocity from the eddy pressure anomaly field relative to 2000m. Finally, we

171   take the curl of the geostrophic velocity field and obtain the relative vorticity $\omega(r,z) = L(r)$

172    $P(z)$, where $L(r)$ is the radial structure of relative vorticity :

173
$$L(r) = \frac{1}{f\rho}\frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial \eta}{\partial r}\right) \tag{8}$$

174   Notice that calculating the radial structure of relative vorticity here does not involve

175   detailed SSH information, we only need the altimeter data for the SLA at the eddy center

176   η_0 and the radius of the eddy R_0, and the universal radial structure of the mesoscale eddies

177   has been found rather stable (S7, S9). The main error source for the relative vorticity is

178   the assumption of level of no-motion at 2000 m. Many eddies in the ACC region have

179 considerable barotropic, non-zero, horizontal velocity at 2000 m. Based the information
180 of Argo float trajectories at their 2000 dbar parking depth, we estimate our calculation of
181 relative vorticity has a relative error at the 15%-20% level.
182   With both ρ_z and relative vorticity evaluated, the three-dimensional PV field can be
183 computed. After projecting the PV distribution onto the isopycnal surfaces, we
184 determine the fluid trapped by the mesoscale eddies by searching for closed PV contours.
185 Due to the relative vorticity and squeezing/stretching of the water column, the PV
186 contours near the core of an eddy can enclose upon themselves, forming closed PV
187 contours. In contrast, the β effect and the large-scale isopycnal slopes of the background
188 PV field works to suppress the formation of closed PV contours. It is the competition of
189 the eddy perturbation PV field versus the large-scale background PV field that determines
190 the area of the fluid trapped by closed PV contours on each isopycnal surface. Figure 2A
191 (2B) in the main text shows the three-dimensional shape of the fluid trapped by a warm-
192 core (cold-core) eddy and the PV distributions on representative isopycnals. Since PV is a
193 dynamical quantity, its close contours and corresponding trapped volume are independent
194 of the eddy propagation speed and the choice of reference frame.
195   Two approximations involved in our estimation of eddy volume need to be clarified.
196 The first is the radial symmetric approximation. The main task of this study is to estimate
197 the eddy-induced transport in a statistical sense, and the radial symmetric approximation
198 has been statistically validated by a former study of altimetry data (S9). The second is we
199 do not consider tilting of the eddy vertical structure. Tilting of the eddy vertical structure
200 is important when considering the tracer transport by mesoscale eddies with a horizontal
201 background tracer gradient. The fluid volume trapped by eddies is determined by areas
202 surrounded by the outermost close PV contours on each isopycnal surfaces; as such, the
203 tilting of eddy vertical structure has little impact on the estimation of eddy-induced
204 volume transports.
205
206 <u>Eddy Propagation Speed</u>
207   Propagation speed of individual eddies can be calculated by tracking their
208 trajectories in sequential altimetry SLA maps (*S6, S9*). In order to obtain the global
209 distribution of the eddy propagation speed, we set up a globally uniform 2° × 2° grid. For
210 each gird, we calculate the eddy propagation speed by averaging the propagation speeds
211 of all eddies within a 4° ×4° average-bin.
212   Figure S1A shows the global distribution of the zonal eddy propagation speed C_x .In
213 Fig.S1B, we compare the average zonal propagation speed from our calculation and that
214 from (*S9*). The two estimates are largely consistent. In most parts of the world oceans,
215 eddies move westward and tend to have a larger speed in lower latitudes. The exception
216 is along the Antarctic Circumpolar Current (ACC) where strong background time-mean
217 current advects eddies eastward.

218   The meridional propagation speed of mesoscale eddies C_y is also calculated and its
219   global distribution is shown in Fig.S2A, and its zonal average is shown in Fig.S2B.
220   Meridionally, mesoscale eddies have a tendency to move poleward within the tropics
221   (20°S-20°N), and equator-ward in the subtropical regions. This tendency is consistent
222   with the average equatorward deflection of all the eddies with lifetimes of 16 weeks and
223   longer in the subtropical regions obtained by (*S9*). While an interesting result, the
224   meridional propagation speed of the mesoscale eddies is one order of magnitude smaller
225   than the zonal propagation speed and, as a result, it plays a less important role in volume
226   transport.
227

228   <u>Global Distribution of Volume Trapped by Mesoscale Eddies</u>
229   For each weekly SLA map, we calculate the volume trapped by each eddy by using
230   the reconstruction method and PV criterion. The altimetry data used in this study contains
231   *N=908* snapshots from Oct 1992 to Jan 2010. For each snapshot and each selected
232   average-bin of 1000 km x 1000 km, the total volume V (unit: m^3) trapped by mesoscale
233   eddies is first calculated. Accumulating the total trapped volume by eddies within the bin
234   for the whole time range from Oct 1992 to Jan 2010, and dividing it by the number of
235   snapshots give the time averaged eddy-trapped volume:

236    $$V_{ave} = \frac{\sum V}{N} \qquad\qquad (9)$$

237   Repeating this process for every grid point lead to the global distribution of V_{ave} (unit: m^3)
238   shown in Fig.S3.
239   Denser eddy population and more fluid trapped by individual eddies lead to a larger
240   average eddy-trapped volume. In the north hemisphere, the average eddy-trapped
241   volume tends to be large on the west side of the ocean basins. Hot spots appear near the
242   west boundary currents, such as the Kuroshio Extension and the Gulf Stream. However,
243   the average eddy-trapped volume tends to be smaller within the cores of the strong
244   background currents when compared with their nearby regions. This is caused by steep
245   sloping of the background isopycnal surfaces along the cores of the western boundary
246   currents. The steep isopycnal sloping leads to a large background PV gradient,
247   suppressing the ability of eddies to trap fluid. In the ACC region, hot spots of the average
248   eddy-trapped volume are all located near the large topographic features. This is likely due
249   to the perturbation of background PV gradient and the enhanced eddy generation near
250   these large topographies.
251

252   <u>Eddy-induced Volume Transport</u>
253   After estimation of the trapped volume V and the zonal propagation speed C_x of
254   individual eddies, we calculate the global distribution of the eddy-induced zonal transport
255   by the following steps. First, we lay out a uniform 2° ×2° global grid, then set up an
256   average-bin with a 10° meridional width and a 20° zonal length around each grid point,
257   and record its zonal length as D_{lon} (unit: m, the length of 20° longitude at each grid point).

258 For every eddy identified in the weekly altimetry maps, the volume transport carried by
259 this eddy is $V*C_x$. Accumulating the total transport by the eddies within this bin for the
260 whole time period from Oct 1992 to Jan 2010, then dividing it by the number of the SLA
261 snapshots, the zonal length D_{lon} and meridional width 10°, give the average eddy-induced
262 zonal transport across the 1°-latitude section:

263
$$Q_x = \frac{\sum V \cdot C_x}{10^o \cdot N \cdot D_{lon}} \qquad (10)$$

264 Figure 3A in the main text shows the global distribution of Q_x in unit of Sv per degree (1
265 $Sv = 10^6 \text{ m}^3 \text{ s}^{-1}$).
266   If we further divide the transport into the eastward component ($Q_x>0$) and westward
267 component ($Q_x<0$), and integrate them over the whole latitude range:

268
$$Q_w(\phi) = \int_{Q<0} Q_x(\phi,\theta) \cdot d\theta \qquad Q_e(\phi) = \int_{Q>0} Q_x(\phi,\theta) \cdot d\theta \qquad (11)$$

269 give the integral eastward transport Q_e and westward transport Q_w, respectively. In
270 equation (11), (ϕ,θ) are longitude and latitude, respectively. We can also compute the
271 meridional integrated transport north and south of 40ºS:

272
$$Q_n(\phi) = \int_{-40}^{80} Q_x(\phi,\theta) \cdot d\theta \qquad Q_s(\phi) = \int_{-80}^{40} Q_x(\phi,\theta) \cdot d\theta \qquad (12)$$

273 and we compare Q_w/Q_e and Q_n/Q_s in Fig.3B.
274   Similar to Q_x, we can also compute the eddy-induced meridional transport Q_y (across
275 the 1°-longitude section) within the same average-bin:

276
$$Q_y = \frac{\sum V \cdot C_y}{20^o \cdot N \cdot D_{lat}} \qquad (13)$$

277 where D_{lat} (unit: m) is the meridional length of the bin. The global distribution of Q_y is
278 shown in Fig.4A. For the meridional transport, we can calculate its zonal integrated
279 transport:

280
$$Q_Y(\theta) = \int_{0}^{360} Q_y(\phi,\theta) \cdot d\phi \qquad (14)$$

281 The zonal integrated eddy-induced meridional transport is shown in Fig.4B. Due to the
282 small meridional propagation speed of eddies; the eddy-induced meridional transport is
283 much smaller than the zonal eddy-induced transport.
284   The main focus of this paper is to estimate the global eddy-induced volume transport
285 in the sense of statistical mean. To quantify the estimation errors on such a global scale is
286 rather difficult. On the other hand, there are independent estimations of eddy-induced
287 volume transport based on *in situ* observations available in some specific regions and this
288 provides us with a chance to indirectly evaluate the error bounds in our estimations.
289 Castelao (*S10*) estimated the eddy-induced onshore transport in the South Atlantic Bight
290 and Gulf Stream Recirculation region (28°N-35°N, west of 75.5°W) to be 7.6 ± 2.2 Sv by

291   combining the altimeter and Argo float data, and our estimated eddy induced transport at

292   the same location is 6.1 Sv. There are also several observations available in the Agulhas

293   Current regions. By combining hydrographic profiles and lower-ADCP data, Gazoli et al.

294   (*S10*) estimated the eddy induced inter-ocean transport from the Indian Ocean into the

295   Atlantic Ocean is about 6-10 Sv. Richardson (*S11*) used the subsurface float and surface

296   drifter data and estimated the eddy induced inter-ocean transport to be about 10-13 Sv.

297   With the altimeter data and assumed eddy vertical structures, Dencausse et al. (S12)

298   estimated the eddy induced Agulhas inter-ocean transport to be about 8.5 Sv. Finally, a

299   recent estimation based on altimeter and Argo floats by Souza et al. (S13) finds the inter-

300   ocean transport at 9 ± 8 Sv. Our estimation of the eddy induced inter-ocean transport is

301   8.2 Sv. From these comparisons, we expect our global estimation of eddy-induced

302   transport to have a relative error about 20%.

303   Finally, there is an assumption in our calculation of SLA at the eddy's center η_0,

304   which ignores the variation of the large-scale SSH field (the seasonal steric signal, for

305   example, is contained in the SLA maps we used). In order to evaluate the influence of

306   this assumption to the eddy-induced transport, we introduce η_a, the difference between

307   the SLA at the eddy's center and the mean SLA around the eddy edges (at $3.5*R_0$ where

308   the eddy perturbations largely vanish) as another metric for eddy amplitude. We choose a

309   snapshot of SLA and identify all eddies in it, then we compare η_0 and η_a of these eddies

310   in Fig.S4A, which indicates the potential relative error in eddy amplitude is about 20%,

311   and this may cause bias and overestimate of the volume trapped by individual eddies.

312   Then we use η_0 and η_a to estimate the volume trapped by these eddies respectively and

313   compare them in Fig.S4B, which indicates the bias in estimating the volume trapped by

314   *individual eddies* is about 25% of its variation. Chelton et al. (*S9*) found that the large-

315   scale SSH variations may be the main cause for this bias. For example, if the large-scale

316   SSHA is positive in a selected region at a given time, it will lead to overestimation of the

317   volume trapped by cold-core eddies and underestimation of the volume trapped by warm-

318   core eddies in the same region. And the negative large-scale SSHA has an opposite

319   effect. Considering there will be both warm/cold core eddies in a region, the bias of

320   volume trapped by warm/cold core eddies will compensate each other when we perform

321   the large-sample statistical average. Thus, we expect the error caused by the variation of

322   large-scale SSH field to the global estimation of eddy-induced transport to be small.

323
